A primary site of infection was identified in 26 (58%) of 45 episodes. The most common primary sites were an infected finger secondary to finger puncture for blood sampling (six episodes), followed in frequency by miscellaneous skin lesions (four episodes), lip lesions (four episodes), infected hyperalimentation lines (three episodes), mouth sores (two episodes), chicken pox lesions (two episodes), and an intravenous catheter, a pierced ear lobe, a biopsy site, a paracentesis site, and a soft tissue abscess (one episode each). Colonization occurred in five other individuals in one or more sites not clinically infected.

Treatment

All patients were initially treated with an aminoglycoside and a cephalosporin or with an aminoglycoside and a semisynthetic penicillinase-resistant penicillin. Frequently, therapy was changed to either a cephalosporin alone or a semisynthetic penicillinase-resistant penicillin alone when the sensitivities were known. The duration of therapy varied from ten days to six weeks, as the patients with infectious complications were treated for longer periods.

Mortality

Four episodes ended fatally. Three were associated with multiple-organism sepsis (Table 1), which occurred four times. Only one episode of single-organism sepsis was fatal. All deaths occurred when the absolute neutrophil count was less than 500/cu cm, and three of the four deaths occurred during relapse of the underlying malignant neoplasm. Fatal episodes occurred twice in children with hematologic malignant neoplasms and twice in children with malignant solid tumors.

Complications During Therapy

Secondary staphylococcal infectious complications of *S aureus* sepsis were seen in nine (20%) of 45 episodes and included liver and abdominal wall abscesses in two episodes, pneumonia in two episodes, meningitis in two episodes, and a chest wall and pleural abscess, multiple soft tissue abscesses, and the scalded skin syndrome seen in one episode each. Secondary complications occurred in both neutropenic and nonneutropenic patients and in both remission and relapse. All of the complications occurred in children with leukemia (Table 2).

In two (22%) of the nine episodes with staphylococcal infectious complications, there was a clearly definable primary focus, compared to the overall population in which 58% had a primary focus. Notably, there were no episodes of acute staphylococcal osteomyelitis or endocarditis.

COMMENT

The incidence of *S aureus* in children with cancer has been estimated to be from 10% to 27%.[7,15] Despite this high incidence, we found a mortality from *S aureus* sepsis alone to be 2%, compared with the mortality described in adults and children without malignant neoplasms, which has ranged from 11% to 78%.[1,2,5,6,16,17] In a previous study of *S aureus* infections in children with cancer, the overall mortality was 30%.[8] However, only 4% could be directly related to *S aureus* infection and 13% were in some part related to *S aureus* infection.[8] Our study confirms that the mortality from *S aureus* sepsis uncomplicated

by a second bacterial or fungal organism is low (one of four cases), as is the overall mortality (four of 45 cases). Multiple-organism sepsis, as in previous studies,[18] was highly fatal, three of four episodes resulting in death. Of the four deaths in our series, all occurred in patients whose absolute neutrophil count was less than 500/cu cm, three of the four occurred in relapse, and three were associated with other infections.

The major complications of *S aureus* infections include endocarditis,[9,10] osteomyelitis,[19] meningitis,[20,21] pneumonia,[22-24] disseminated abscesses,[25] and the scalded skin syndrome.[26] In a review of a series of *S aureus* sepsis, Cluff et al found that 35% of individuals had metastatic staphylococcal abscesses demonstrated by roentgenogram, surgical drainage, or at postmortem examination.[5] Nolan and Beaty[2] reviewed 105 cases of *S aureus* bacteremia and found two clinical patterns, separable according to the presence of an identifiable primary staphylococcal infection. Of the patients in their series who had a primary site, the incidence of endocarditis or of a secondary staphylococcal focus was very low, whereas bacteremia not associated with a primary site was associated with a high incidence of endocarditis and secondary foci of staphylococcal infections. Furthermore, Iannini and Crossley[11] reviewed 29 cases of *S aureus* bacteremia associated with a removable focus of infection and found no cases of endocarditis or secondary foci of infection. As in a previous review,[8] a primary site of infection was common in our patients, occurring in 26 (58%) of 45 episodes. However, of these 26 patients, only two (8%) had a secondary staphylococcal complication, whereas of the 19 patients without a primary site, seven (37%) had a secondary infectious complication. These observations support the findings of the two previous adult series[2,11] that an *S aureus* bacteremia associated with a removable focus of infection or with a primary site is usually not complicated by a secondary site of infection.

Although endocarditis was not found by clinical or laboratory evaluation or by autopsy examination, secondary complications of staphylococcal infections in our series occurred in nine (20%) of 45 episodes. This was much higher than the three secondary staphylococcal complications seen in a series of 70 episodes of *S aureus* bacteremia in children with cancer reported by Ladisch and Pizzo.[8] Further evaluation of the secondary staphylococcal complications in our series revealed no differences in therapy and no relationship to absolute neutrophil count or remission status. All complications occurred in children with leukemia.

The low mortality may have been related to early institution of antibiotic therapy. However, the morbidity was appreciable, and prompt treatment with antibiotics did not prevent secondary staphylococcal complications. Children with *S aureus* bacteremia who have been treated with immunosuppressive therapy must be watched closely for complications and secondary foci of staphylococcal infection, especially when there is no primary site of infection.

Immunoglobulin Concentrations in Duodenal Fluid of Infants and Children

Emanuel Lebenthal, MD; Barry A. Clark; Ok Kim

• **The immunoglobulin content of duodenal fluid in children at different ages has not as yet been determined, while that of serum, feces, and saliva has been well established. In 92 normal infants, children, and young adults on whom duodenal intubation was performed, duodenal fluid IgA, IgM, and IgG levels were measured. From these data, a developmental profile of immunoglobulins in duodenal fluid from 2 weeks of life to 19 years was obtained. Duodenal fluid IgA, IgM, and IgG appeared to maintain rather constant levels. The grand mean IgA level was lower than the grand mean IgG level (12.7 ± 0.8 vs 29.1 ± 2.5 mg/g of protein). Secretory component was detected in all duodenal fluids. IgG concentrations were greater than those of IgM (29.1 ± 2.5 vs 13.2 ± 1.4 mg/g of protein) over all age ranges. The developmental patterns of all immunoglobulins appeared to be different from those observed in serum or saliva with the exception of duodenal fluid IgA, which has a pattern similar to that of salivary IgA.**

(*Am J Dis Child* 134:834-837, 1980)

Immunoglobulins found in duodenal fluid have been reported to originate from gastric,[1] pancreatic,[2] bile,[3] and small intestine secretions.[4] The pathways for transepithelial transfer of these immunoglobulins have not been completely defined.[5] To our knowledge, the age-related changes of duodenal fluid immunoglobulins have not been reported, while those of serum,[6] feces,[7] and saliva[8,9] have been observed.

Serum IgA has generally not been detected in newborns, and serum IgM has been found only in small amounts.[6] IgG has been found to be the predominant serum immunoglobulin in infancy.[6] IgA levels in human fecal material were very low in the newborn.[7] In the saliva, IgA has not been detected until 1 week of age, while IgG has been found to be present only temporarily.[8] Human salivary IgM has not been detected at any age.[8]

Estimates of immunoglobulin concentrations in the upper small intestine varies considerably among researchers.[4,10,11] It is the aim of this report to provide an overview of the development of immunogobulins in the normal human duodenum from 2 weeks to 19 years of age. In addition, the reliability and validity of the determination and the technique of fluid collection were investigated.

SUBJECTS AND METHODS

Subjects

A group of 92 infants and children, between the ages of 2 weeks and 19 years, were selected as normal subjects from approximately 250 patients undergoing pancreozymin-secretin testing. Informed consent was obtained from all parents of infants and children undergoing the pancreozymin-secretin test as well as measurement of pancreatic enzymes and immunoglobulins. The subjects included 24 infants, 1 month of age and older, who were siblings of patients with cystic fibrosis, investigated under a special protocol, and found to be disease-free. The largest number of subjects (68) came from a group of patients evaluated for failure to thrive or history of chronic diarrhea and found to have no gastrointestinal disease. They had no evidence of pancreatic disorders or small intestinal mucosal injury. All subjects in this study had normal serum albumin and globulin levels. There was no appreciable difference between these two groups with respect to the variables measured in the study. The assignment of age groups was arbitrary according to Haneberg and Aarskog.[7]

Handling of Duodenal Fluids

After an overnight fast, duodenal intubation was performed under fluoroscopic control, using a double-lumen Dreiling tube. The tip of the tube was positioned in the area of the ligament of Trietz.[12] In newborn infants receiving nasojejunal feeding, a gastric tube was added after four hours of fasting. Duodenal fluid was collected for 20 minutes in flasks cooled on ice. At times, gentle aspiration was used to collect the specimens. The specimens were immediately frozen and stored at −20 °C.

Quantitation of Immunoglobulins

IgG, IgA, and IgM were quantitated by single radial immunodiffusion techniques of Mancini,[13] by use of commercially available equine or goat antisera that were monospecific for the heavy chains of human IgG, IgM, and IgA (7S).

All determinations of IgA in duodenal fluid were carried out using goat antibodies against 7S IgA. Colostrum was used as a standard in an attempt to determine the percentage of antibodies that are 7S and 11S.

The Fahey-McKelvey technique[14] was used to construct standardization curves correlating the concentration of immunoglobulins in the duodenal fluid sample with its corresponding precipitation ring diameter. Semilogarithmic paper was used to produce a linear relationship between the two variables. The plates were incubated at 23 °C and read at 18 ± 0.5 hours after the wells had been filled.

Quality Control Analysis

Lyophilized human serum and colostrum were used as a quality control measure. The data were well within the standardization range of each immunoglobulin. A number of samples were thawed after storage at −20 °C for five to six months to determine immunoglobulin loss during storage. There was no significant difference. Several of the subjects' test results were examined for evidence of any variation within each group of the examination and found to be consistent.

The presence of secretory component in the duodenal fluid was tested by use of double radial immunodiffusion plates (Ouchterlony 1% agar gel). Rabbit antiserum to human IgA (α chain) was placed in the center wall of one plate (Fig 1, top), and rabbit antiserum to human secretory component was placed in the center well of another plate (Fig 1, bottom). The specimens (duodenal fluid, human pooled serum, colostrum, saliva, and amniotic fluid) were placed in each of six outside wells; their cross reactivity with the antiserum was checked after incubation for 12 to 24 hours at room temperature.

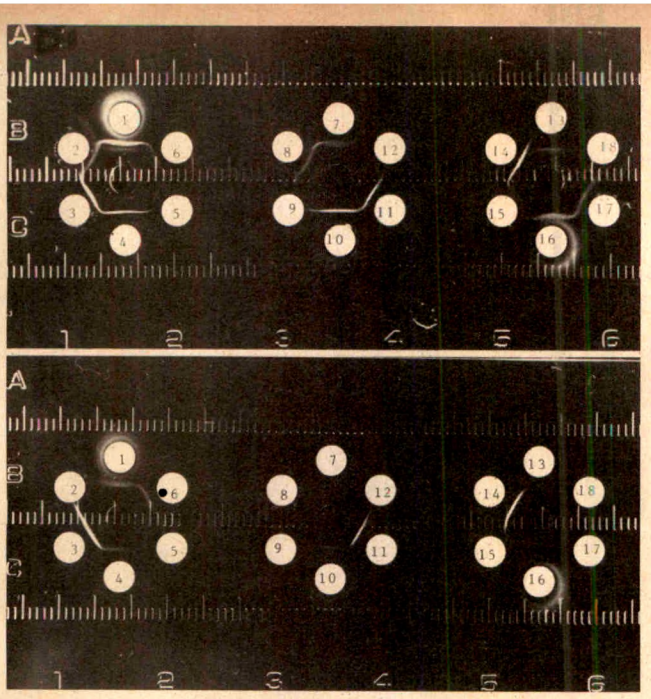

Fig 1.—Top, Double radial immunodiffusion with rabbit antiserum to human anti-IgA (α chain) in center wells. Bottom, Double radial immunodiffusion with rabbit antiserum to human secretory component in center wells. Outer wells were numbered and contained following substances: wells 1, 4, 7, 10, 13, and 16, duodenal fluids from children aged 4 to 16 months; wells 3, 11, and 14, human colostrum; wells 5, 12, and 18, human amniotic fluid obtained at 28 to 42 weeks' gestation; wells 6, 9, and 15, human saliva from children aged 2 to 12 years; wells 2, 8, and 17, human serum from children aged 2 to 17 years.

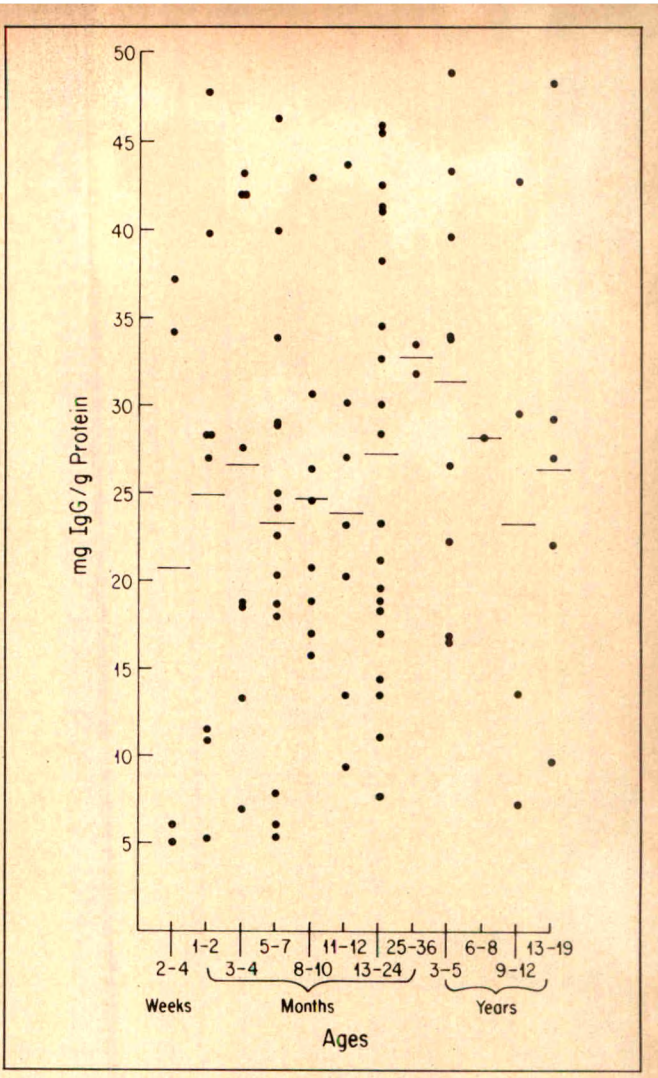

Fig 2.—Human duodenal fluid IgG levels from 2 weeks to 19 years of age.

The possible continued alteration of immunoglobulins in the duodenal fluid during the incubation period due to the presence of endopeptidases and exopeptidases secreted by the pancreas was tested.

A sample control of fixed-ratio serum and duodenal fluid immunoglobulin were incubated. No significant changes were observed in the immunoglobulin levels.

Statistical Analysis

Analysis of the data was performed to determine differences in concentrations of IgA, IgM, and IgG that might exist between age groups. Analysis was accomplished by a one-way multivariate analysis of variance[15] for three dependent variables (IgA, IgM, IgG) across 13 age groups (1 × 13 MANOVA). The analysis was executed by means of a prepared statistical computer program that simultaneously performs univariate analyses of variance for each dependent variable (1 × 13 ANOVA).

RESULTS

Double radial immunodiffusion with rabbit antiserum to human anti-IgA (α chain) (Fig 1, top) demonstrated precipitation lines in all the duodenal fluids, human colostrum, and human serum tested. Human saliva and amniotic fluid showed faint precipitation lines. Double radial immunodiffusion with rabbit antiserum to human secretory component (Fig 1, bottom) demonstrated heavy precipitation lines with colostrum. Less pronounced lines were seen with human duodenal fluid and saliva. No precipitation lines were observed with human amniotic fluid or serum.

The values obtained for each immunoglobulin at each age are seen in Fig 2, 3, and 4. The data are presented per grams of protein and per deciliters of fluid. The results of the 1 × 13 MANOVA indicated that no statistically significant differences existed between any of the age groups (F [36,115.96] = 1.117; $P < .47$), although significant differences existed between the values of the various immunoglobulins (F [3,39] = 112.07; $P < .0001$). The concentration of protein in duodenal fluid ranged from 0.34 to 0.81 g/dL, with a mean of 0.52 g/dL.

IgG Levels in Duodenal Fluid

The concentration of IgG per gram of protein maintained a rather constant level throughout the age ranges studied (ANOVA: F [12,41] = 1.03; $P < .43$). No statistical significance was noted between the ages. IgG concentrations were also observed to be higher than those of either IgA or IgM over all age ranges (ANOVA: F [1,41] = 23.867; $P < .0001$) (Fig 2, 3, and 4).

The concentration of IgG per deciliter of fluid showed a similar level throughout the age ranges studied. IgG levels per deciliter of fluid were also observed to be higher than either IgA or IgM levels.

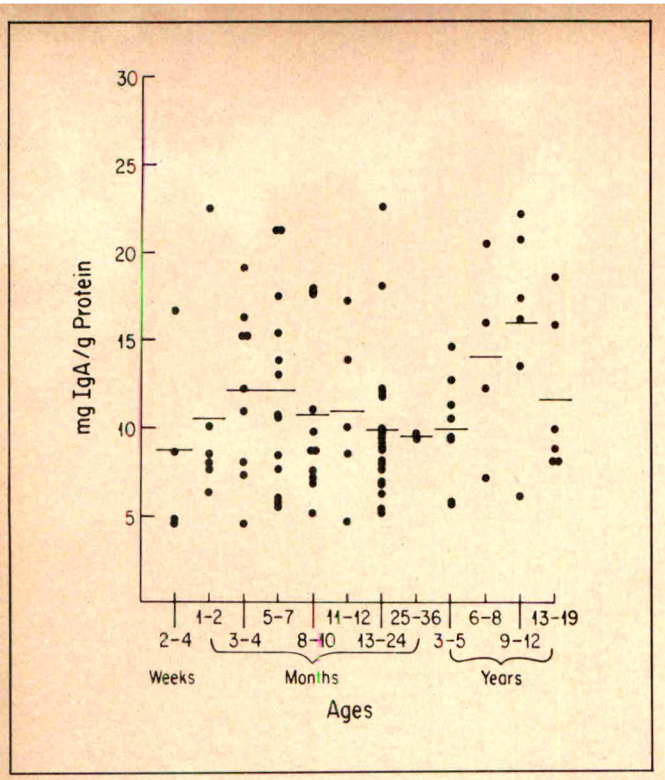

Fig 3.—Human duodenal fluid IgA levels from 2 weeks to 19 years of age.

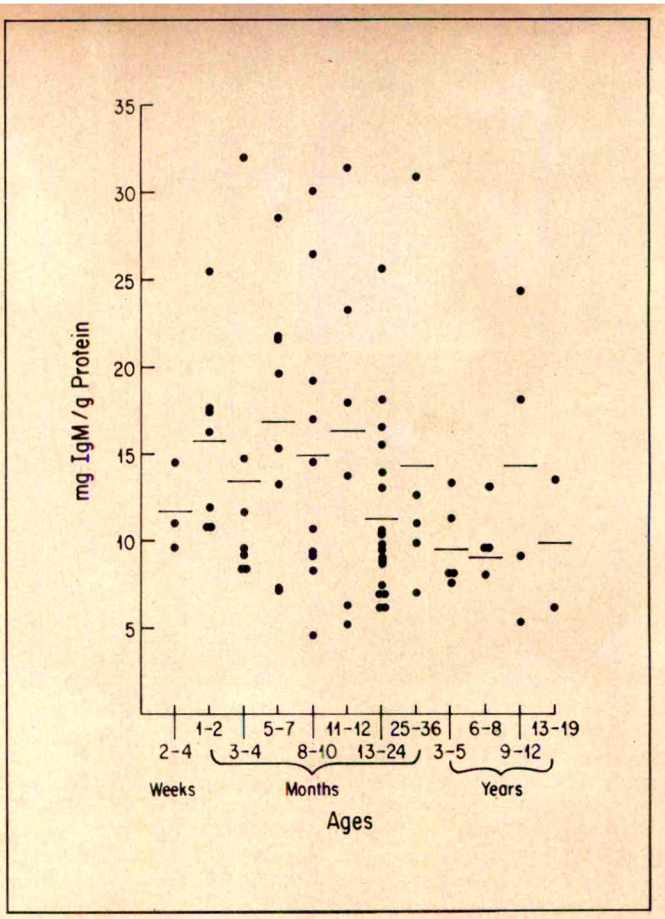

Fig 4.—Human duodenal fluid IgM levels from 2 weeks to 19 years of age.

IgA Levels in Duodenal Fluid

The IgA levels per gram of protein in duodenal fluid were similar in all age groups studied (ANOVA: F [12,41] = .68; $P < .75$).

IgA levels per deciliter of fluid also maintained similar levels throughout the studied ages.

IgM Levels in Duodenal Fluid

As with IgA levels, the levels of IgM per gram of protein in duodenal fluid persisted through all the ages tested (ANOVA: F [12,41] = 183; $P < .62$).

Similar results were obtained with IgM per deciliter of fluid, where a similar level was observed over all ages studied.

COMMENT

There is concern with the techniques used in duodenal fluid immunoglobulin analysis. Shearman and colleagues[16] have reviewed the problems of accurate quantitation of immunoglobulin concentrations in the intestinal fluid. Immunoglobulins are susceptible to proteolytic digestion: IgA to pepsin and IgG and IgM to trypsin.[17] A number of techniques have been used in attempting to overcome this problem. They include heating, cooling, and the addition of antitryptic agents.[18] None of these precautions has met with complete success, as evidenced by the presence of immunoglobulin fragments in duodenal secretions.[17] This indicates that some proteolysis may have taken place and may lead to overestimation of immunoglobulin concentrations, with only semiquantitative results being obtained. The developmental patterns of duodenal fluid immunoglobulin levels remain unchanged as all levels are assumed to be affected equally.[12] The specimens used in this study were frozen immediately after collection to minimize deterioration of immunoglobulin content that would adversely effect the results. There is a possibility of continued alteration of Ig molecules by duodenal enzymes during the radioimmunodiffusion procedure. To test this possibility, we inoculated a fixed ratio of serum with duodenal fluid of known Ig quantity and found no changes in the expected values.

We observed double precipitation rings in 7% of the single radial immunodiffusion testing plates. These rings were reported by Plaut and Keonil[18] and Kraft et al.[19] The rings are presumed to be nonspecific precipitation lines between antisera and a mucopolysaccharide in the duodenal fluid.[19] These plates were not included in compiling the final data.

Serum IgA in man is predominantly a 7S monomer, while secretory IgA, as found in duodenal fluid and saliva, is predominantly an 11S dimer. As stated earlier, all the samples used in this analysis contained secretory component. In the quantitation of IgA in duodenal fluid, the IgA reference serum is of the 7S variety, while the IgA in the specimen is both 7S and 11S. This, therefore, must lead to an underestimate of the duodenal fluid level of IgA. Hobbs,[20] studying pure 11S IgA as found in human saliva, reported a correction factor of 1.4 to determine the correct IgA level. However, duodenal fluid IgA contains both 11S and some 7S IgA.[5] We used known amounts of 11S IgA in colostrum as a standard and corrected the 7S IgA standard of the available antisera.

The sources of IgA and IgM that

enter the duodenum are believed to be the plasma cells located in the lamina propria of the intestinal mucosa.[21-23] These immunoglobulins have been assumed to interact with secretory component, a receptor on the surface of or within intestinal cells in the crypt region, after diffusion across the basement membrane.[24] Subsequently, it was suggested that IgA and IgM are transported through the epithelial cell and secreted into the duodenum by exocytosis.[25] The source of IgG in the duodenum has been assumed to be the serum, as the mucosa contains relatively few IgG-containing cells.[23] IgG enters the lumen of the duodenum by the same nonspecific mechanism common to other plasma proteins.[25]

In this study, there was no statistical difference in duodenal fluid immunoglobulin concentrations from 2 weeks through 19 years of age. The IgA developmental patterns were found to be different from those seen with IgA in serum.[6] IgG levels were approximately twice those of IgA or IgM.

The development of immunoglobulins in human serum from infancy through adulthood has been well established.[6,26-29] IgA has been detected in the cord sera of some infants. Serum IgA levels increase over the first months of life to reach almost one quarter of the adult levels by the age of 1 year, and 50% of the adult levels by 3½ years of age.[26] Serum IgG levels drop during the first four months of life to approximately one half of the adult level and thereafter increase rapidly up to 1 year of age, finally reaching adult levels by the age of 7 years.[6] Serum IgM concentrations are very low at birth, but increase steadily so that 50% of adult concentration is reached at 4 months of age, and adult levels are attained at approximately 1 to 2 years of age.[6]

Haneberg and Aarskog[7] measured IgA in human fecal material and demonstrated minimal levels of antibody at 1 to 3 days of life. This was followed by a rapid increase in IgA level to a peak at 1 to 2 months of age and a constant level was then observed at a value approximately one-fifth the peak value.[7] This plateau occurred at 1 year of age and continued as such into adult life.[7]

Selner et al[8] measured the concentration of immunoglobulins in human saliva. IgA was not detected at birth, but appeared by 1 week of life. By 4 weeks of age, 92% of the infants had adult levels of IgA in their saliva. IgM was not detected. IgG was temporarily present in the saliva prior to 10 days of age, but disappeared as IgA concentrations increased.[8] It was postulated that this temporary IgG level in the saliva may represent "leakage" from the serum due to the increased permeability of the mucous membranes to protein during the early postnatal period.[8,30,31] Brandtzaeg et al[9] reported IgA concentrations in human saliva predominating over those of IgG.

In our studies, the pattern of development for IgG, IgA, and IgM in duodenal fluid was quite different from that reported for human serum.[6,27,29] IgA and IgM levels in duodenal fluid remained relatively constant through the age ranges studied. In our study and in other observations,[21-23] IgM is present in duodenal fluid. This is in contrast to saliva, in which IgM was not detected at any age.[30] In addition, the developmental patterns observed with salivary IgA represent sequences similar to those seen with duodenal fluid IgA.[8]

This investigation was supported in part by the National Dairy Council.

W. Allan Walker, MD, reviewed the manuscript. Pearay L. Ogra, MD, and Byung Hak Park, MD, helped design and execute the project and also reviewed the manuscript. Gary Graber, PhD, did the statistical analysis. Mary Lou Stein provided secretarial assistance.

5-Hydroxytryptophan and Pyridoxine

Their Effects in Young Children With Down's Syndrome

Siegfried M. Pueschel, MD, MPH; Robert B. Reed, PhD; Christine E. Cronk, MA, MS; Beth I. Goldstein

• In a double-blind study, 89 children with Down's syndrome were given 5-hydroxytryptophan or pyridoxine hydrochloride in the first three years of life. The analysis of 5-hydroxyindole blood levels revealed that 5-hydroxytryptophan, pyridoxine, and the combination of 5-hydroxytryptophan and pyridoxine raised blood levels of 5-hydroxyindole equally well in 40% of the children. The assessment of muscle-tone ratings showed no significant difference among the study groups once children with moderate and severe congenital heart disease were excluded. Detailed studies of cognitive-adaptive function of children in the various groups found a significant difference on the Vineland Social Maturity Scale at ages 6, 12, 18, and 36 months; yet the source of significance was a negative interaction affecting children whose parents were able to comply with furnished guidance; these children showed consistently higher levels of accomplishment.

During the past decades a multitude of treatment modalities for Down's syndrome have been reported.[1-10] In the attempt to improve physical features and mental abilities of the child with Down's syndrome, a variety of medications, including hormones, vitamins, sicca cells, dimethyl sulfoxide, and various combinations of these and other compounds, have been used. The ineffectiveness of the majority of those therapeutic approaches has been discussed in recent publications.[11-13]

5-Hydroxytryptophan was introduced as a form of therapy in Down's syndrome shortly after several investigators had reported decreased 5-hydroxytryptamine (serotonin) levels in peripheral blood in children with this syndrome.[14-19] Bazelon and co-workers noted improvement in muscle tone, reduced tongue protrusion, and increased motor activity in infants with Down's syndrome who had been given 5-hydroxytryptophan.[20] In a subsequent study, the same investigator compared a group of children with Down's syndrome who received 5-hydroxytryptophan with children in a placebo group; no significant difference of development between children in these two groups was found.[21] In 1971, Partington and co-workers reported a controlled trial of 5-hydroxytryptophan administration to children with Down's syndrome. These investigators did not detect any improvement in motor, behavioral, and neurological functions.[22] Weise and co-workers who gave 5-hydroxytryptophan to young children with Down's syndrome also observed that this compound was not effective in accelerating the children's rate of development. Moreover, no discernible behavioral differences between treated and nontreated children were noted.[23]

Encouraged by Bazelon's initial results, the investigations reported here were begun before the previously cited studies were published.[21-23] The primary objective of this study was to evaluate the effects of 5-hydroxytryptophan or pyridoxine hydrochloride administration on motor, social, intellectual, and language development in young children with Down's syndrome.

SUBJECTS AND METHODS

Newborn children with Down's syndrome were recruited from maternity hospitals and obstetric services of general hospitals located in the greater Boston area, other parts of Massachusetts, southern New Hampshire and Vermont, northern Connecticut, and Rhode Island. Before the individual child entered the study, his or her parents were informed of the study's basic goals, its experimental nature, and the double-blind design. The known risks and possible side effects of 5-hydroxytryptophan were explained and those parents who agreed to have their child enrolled in the study signed an approved informed consent form.

In addition to 5-hydroxytryptophan, the administration of pyridoxine (a coenzyme that participates in the decarboxylation of 5-hydroxytryptophan to 5-hydroxytryptamine) had been reported to increase levels of 5-hydroxytryptamine in children with Down's syndrome.[21] To evaluate the individual as well as the combined and interactive effects of 5-hydroxytryptophan and pyridoxine, four study groups were designed: placebo, pyridoxine, 5-hydroxytryptophan, and 5-hydroxytryptophan-pyridoxine. Random assignment to the different study groups was done by our biostatistical consultant from the Harvard School of Public Health, Boston, and transmitted directly to the participating pharmacist so that the evaluation team was unaware of the random assignment.

The various compounds, placebo, pyridoxine, 5-hydroxytryptophan, and 5-hydroxytryptophan-pyridoxine, were provided in capsules indistinguishable from each other and were administered in divided doses of 1 to 2 mg/kg/day of 5-hydroxytryptophan and 5 to 10 mg/kg/day of pyridoxine hydrochloride. The initial dosage was low (1 mg/kg/day of 5-hydroxytryptophan and 5 mg/kg/day of pyridoxine hydrochloride). If no side effects were observed, the dosage was gradually increased to its maximum (2 mg/kg/day of 5-hydroxytryptophan and 10 mg/kg/day of pyridoxine hydrochloride).

A total of 114 newborns with Down's syndrome were admitted to the study during a three-year time period and each child was followed up until his or her third birthday. Of the 114 children, 25 were excluded for various reasons: 13 children died during the course of the study, 12 of whom had had severe congenital heart disease. Ten children withdrew from the study; their parents either had moved out of the area or had had serious social problems that interfered with orderly follow-up. Two other children were excluded from the study; one had mosaic Down's syndrome and the other child's data were incomplete at the time of the study's completion.

Of the 89 children in the final study sample, there were 50 boys and 39 girls. Eighty-six children's karyotypes showed trisomy 21 and three children had D/G translocation Down's syndrome.

After breaking the drug code at the end of the study, it was found that there were 20 children in the placebo group, 23 in the pyridoxine group, 22 in the 5-hydroxytryptophan group, and 24 in the 5-hydroxytryptophan-pyridoxine group. As Table 1 shows, the random assignment of children to the study groups placed more children with moderate and severe congenital heart

disease in the placebo group (seven children) than in the 5-hydroxytryptophan group (one child). Therefore, in making certain specified analyses, children with moderate and severe cardiac conditions were excluded.

Consideration was given to factors that might have influenced the development of the young children with Down's syndrome during antenatal and perinatal periods. Tables 2 and 3 gives summary statements of selected variables, which indicate that there was acceptable comparability among the randomized study groups, and no significant difference was found except that the mean birthweight of children in the 5-hydroxytryptophan group was significantly lower than the mean birth weight of children in the other study groups. However, during the remainder of the study period there was no statistically significant difference of mean weights of children in the four study groups.

Laboratory investigations performed at three-month intervals focused primarily on total 5-hydroxyindole determination in the blood of all infants with Down's syndrome. This was done according to the procedures described by Rosner and co-workers,[14] which is a modification of Udenfriend et al's previously reported method.[24] The 5-hydroxytryptamine content in the total 5-hydroxyindole determination is 99%, and 1% is 5-hydroxyindole acetic acid.[25] At the end of the study, several parents did not want blood taken from their children, so that only limited laboratory data were available beyond the 24 to 30 month period.

The muscle tone of the children in the study was evaluated independently by three examiners: pediatrician, neurologist, and physical therapist, each of whom followed his or her individual protocols. During the physical examinations, the pediatrician recorded a composite score for muscle tone, ranging from 0 (extremely poor muscle tone) to 4 (hypertonic). The neurologist rated separately muscle tone of upper extremities, lower extremities, neck, and trunk; in addition, posture, arm recoil, leg recoil, ventral suspension, and traction responses were recorded. The individual assessments were averaged to produce a single muscle tone score for each examination. The physical therapist focused on resistance against passive movements in trunk, hip, knees, and elbows. An average score was obtained from each examination.

The cognitive-adaptive function of children in the study was evaluated using the Bayley Scales of Infant Development[26] and the Vineland Social Maturity Scale.[27] Both instruments were given at six-month

intervals during the study period. At the third birthday, each child's language abilities were examined using the Receptive-Expressive Emergent Language Scale (REEL).[28]

Support to parents and instructions regarding various aspects of care and stimulation were provided throughout the study.[29] The parents' ability to comply and follow through with the furnished guidance was rated as *yes* or *no* by the participating nurse after lengthy interviews with the parents at six-month intervals. The individual ratings were summed in the final analysis of the data.

RESULTS

In the analysis of the total 5-hydroxyindole concentration in blood of children with Down's syndrome, it became apparent that 5-hydroxytryptophan, pyridoxine, and 5-hydroxytryptophan-pyridoxine all raised the levels in blood to an equal degree (Fig 1). The effect of pyridoxine alone was similar to the effect of 5-hydroxytryptophan, and the combination of 5-hydroxytryptophan-pyridoxine was not more effective than each of the individual "medications." There was a gradual decline of 5-hydroxyindole blood levels over time in the treatment groups as well as in the placebo group, although the latter trend was less marked (Table 4 and Fig 1).

In each of the three treatment groups, the effect on total 5-hydroxyindole blood levels was confined to about 40% of the children, whereas the remaining children had mean 5-hydroxyindole blood levels within the range of the placebo group (Table 5). This was not influenced by other conditions, such as congenital heart disease or parental compliance.

Muscle tone examinations done by pediatrician, neurologist, and physical therapist showed a good interexaminer agreement, with an average correlation of 0.55. The examiners observed a gradual increase of muscle tone in children in all of the groups over the study period (Fig 2).

Children who had been randomly assigned to the 5-hydroxytryptophan group initially had higher muscle tone ratings than children in the other two treatment groups and in the placebo group, but the difference was not statistically significant. The slightly increased muscle tone in children from the 5-hydroxytryptophan group as compared with the other three groups continued throughout the study. The muscle tone ratings by the pediatrician during the second and third year of study were noted to be significantly higher in children in the 5-hydroxytryptophan group. However, when children with moderate and severe cardiac disease were excluded, no significant difference was observed among the four study groups (Fig 2).

It has been noted previously that the 5-hydroxyindole blood levels had been elevated in about 40% of the children in the three treatment groups, whereas the remainder of the children in the treatment groups maintained blood levels comparable to the placebo group. Consequently, the 27 children with highest average blood levels were studied to determine whether possible effects of treatment had been confined to these apparent responders.

When the muscle tone analysis was carried out contrasting children with high (> 175 ng/mL) and low (< 175 ng/mL) total 5-hydroxyindole blood levels, no significant difference was noted. In further analyses, the treatment effects were studied for each of 21 measures of cognitive-adaptive function from the Bayley Motor, Bayley Mental, and the Vineland Social

Table 5.—Distribution of Children With Down's Syndrome According to Mean 5-Hydroxyindole Blood Level and Study Group

5-Hydroxytryptophan-pyridoxine	12	12	24
Total	**47**	**42**	**89**

*$\chi^2 = 7.48$; df 3; $P < .10$.

Maturity Scales at ages 6, 12, 18, 24, 30, and 36 months, and the REEL vocabulary measures at 36 months. There were no statistically significant treatment effects for the Bayley tests or for the REEL examinations at the .05 level when comparing the four study groups. The only findings that were statistically significant occurred on the Vineland Social Maturity Scale at ages 6, 12, 18, and 36 months ($P < .05$) for the overall F test. At 6, 12, and 18 months of age, the source of significant findings was a negative interaction, ie, the children given 5-hydroxytryptophan-pyridoxine performed less well than would have been expected on the basis of 5-hydroxytryptophan and pyridoxine groups. At 36 months of age, the negative interaction on the Vineland Social Maturity Scale was not significant by itself. However, the pattern of effects was the same as at the earlier ages of 6, 12, and 18 months, when there was a slight positive effect of 5-hydroxytryptophan, a slight negative effect of pyridoxine, and negative interaction (Table 6).

Since there is no biochemical basis for expecting or interpreting the negative interaction effect, it was decided to investigate other possible explanations for this peculiar aspect of the data. Subsequently, parental compliance, a nonrandomized variable, was introduced into further analyses. Table 7 gives the compliance data according to study group. While χ^2 analysis did not show a significant difference among the groups ($P > .10$), there is a disproportionate number of "good" compliance cases in the 5-hydroxytryptophan group. Forty-two children whose parents had been less able to comply with furnished guidance were placed in one group and 47 children whose parents carried out recommendations successfully were placed in the other group. There was no evidence of drug effect in the latter group. However, in the former group of children whose parents had difficulties with compliance, the statistically significant negative interaction on the Vineland Social Maturity Scale at ages 6 and 18 months was noted. The group of children whose parents were rated as successful showed consistently higher levels of accomplishment than children in the other group with "poor" compliance, as shown in Table 8. Thus, it seems that if there was any positive drug effect, it was overshadowed by the parental compliance variable. Moreover, analysis of cognitive-adaptive function comparing children with relatively high 5-hydroxyindole blood levels with those of lower 5-hydroxyindole blood levels showed no significant treatment effects.

COMMENT

The failure of past attempts at treatment of children with Down's syndrome are in part due to the complexities and the many unknown elements involved in the pathogenesis of

symptoms and signs in Down's syndrome.

Cognizant of these factors, the rationale of this study was based on the facts that 5-hydroxytryptamine plays an important neurophysiological role as a regulatory amine, that 5-hydroxyindole blood levels are 30% to 50% lower in the newborn child with Down's syndrome, that the 5-hydroxytryptamine concentration can be raised by administration of its precursor 5-hydroxytryptophan, and that 5-hydroxytryptophan administration was reported to increase muscle tone of the child with Down's syndrome. It was hypothesized that the increased muscle tone and enhanced motor activity in children with Down's syndrome receiving 5-hydroxytryptophan would lead to augmented environmental exploration by the child with proportionally greater sensory input, which in turn might be beneficial to his overall development.

As noted in Fig 1, the administration of pyridoxine, hydroxytryptophan, and the combination of 5-hydroxytryptophan-pyridoxine all raised the total 5-hydroxyindole blood level in 40% of the children in the treatment groups. Why did the remaining 60% of the children in the treatment groups not have elevated total 5-hydroxyindole blood levels? Since we made frequent spot checks concerning parental compliance of the administration of the medications, we knew that the vast majority of parents (> 95%) gave the children the medication. Laboratory errors and pharmacy miscalculations as responsible elements for this finding are highly unlikely. Decreased absorption from the intestinal tract may in part account for the low total 5-hydroxyindole blood levels in some children who received the medications.[30] Although some investigators have reported deficiencies in the 5-hydroxyindole pathway (see Fig 3), there is good evidence that this pathway is essentially intact in children with Down's syndrome.[21] It is more likely that failure of 5-hydroxytryptamine uptake, transport, or binding, in addition to limited availability of adenosine triphosphate, may selectively be responsible for the low total 5-hydroxyindole blood concentration in some children of the treatment groups.[31-34] It is also possible that some unidentified metabolic factor made some children respond to the administration of the three compounds in raising 5-hydroxyindole levels, whereas in other children the total 5-hydroxyindole blood levels were not affected by the administration of 5-hydroxytryptophan, pyridoxine, or 5-hydroxytryptophan-pyridoxine.

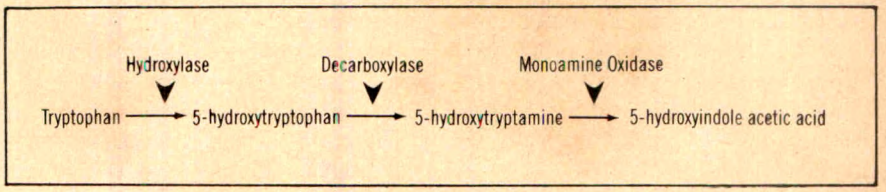

Fig 3.—5-Hydroxyindole pathway.

Compared with Coleman and Steinberg's study,[21] the placebo group in this investigation had higher 5-hydroxyindole blood levels, yet the treatment groups, as noted earlier, had similar total 5-hydroxyindole blood levels as children in Coleman and Steinberg's study who received 5-hydroxytryptophan.[21] They also observed that in some children the 5-hydroxyindole level was significantly raised by 5-hydroxytryptophan administration, whereas in others the 5-hydroxyindole levels were only minimally higher.

It is generally agreed that the conventional assessment of muscle tone is not an accurate science. Therefore, we attempted to objectively quantify the muscle tone of children with Down's syndrome by computerized electromyography; however, these efforts failed. Thus, the examiners assessed the muscle tone in the usual fashion, yet, good correlation was found among the three examiners' individual assessments.

Bazelon et al had initially reported that 5-hydroxytryptophan administration would increase markedly the reduced muscle tone in children with Down's syndrome.[20] In a second study, only a mild increase in muscle tone was noted in children with Down's syndrome who had received 5-hydroxytryptophan during the first few months of life; moreover, after age 4 months, children in the placebo group even tended to have higher muscle tone ratings than children in the treatment group.[21] Similarly, Partington and co-workers as well as Weise and co-investigators, who had administered 5-hydroxytryptophan to children with Down's syndrome, did not find a consistent effect or long-term improvement of muscle tone in their patients.[22,23]

Of primary interest are the results of the cognitive adaptive assessments. A selective, simple analysis of the data could have been interpreted as showing that hydroxytryptophan had

a positive effect enhancing the adaptive function of the child with Down's syndrome, since on the Vineland Social Maturity Scale at 6, 12, 18, and 36 months a statistical significance was found. However, this effect was primarily due to an uninterpretable negative interaction of pyridoxine and 5-hydroxytryptophan. Moreover, when children with moderate and severe cardiac disease were excluded from the analysis and the potential compliance variable was taken into consideration, no significant difference among the children's cognitive-adaptive function was apparent. Although our study has analyzed in much more detail various aspects of the Down's syndrome child's abilities, it is in agreement with previously reported negative results of the administration of 5-hydroxytryptophan to children with Down's syndrome.[21-23]

In an attempt to explain the negative findings in children who were given tryptophan compounds, their known effects on the CNS need to be discussed. It is conceivable that the same defect observed in transport, uptake, and binding of 5-hydroxytryptamine in platelets also exists in the neurons. Although several studies suggested normal synthesis of 5-hydroxytryptamine in the CNS,[35,36] Fellstrom and co-workers reported low levels of 5-hydroxyindoleacetic acid in the CSF of Down's syndrome children.[37] Yet, it is uncertain whether 5-hydroxyindole compounds measured in spinal fluid accurately reflect concentration of 5-hydroxytryptamine at the neuronal level.

No controlled studies are available on 5-hydroxytryptophan and 5-hydroxytryptamine transport across the blood-brain barrier. Even if 5-hydroxytryptophan administered to children with Down's syndrome were transported adequately into the CNS, we still would lack information on how increased 5-hydroxyindole compounds in the CNS would affect the overall mental functioning of these children.

Mitogenic Response to *Toxocara* Antigen and Chemotactic Defect in Visceral Larva Migrans

Kenneth Caldwell, MD; Michael Lobell, MD; Pater F. Coccia, MD

• A 3-year-old girl had the typical features of visceral larva migrans syndrome, including hypereosinophilia, recurrent pulmonary infiltrates, and elevated serum IgG, IgE, and isohemagglutinin titers. A marked mitogenic response of her cultured lymphocytes to *Toxocara* antigen but not to *Ascaris* antigen was found. A neutrophil chemotactic abnormality to *Escherichia coli* culture filtrates and zymosan-activated sera was also demonstrated, which partially corrected after she was treated with diethylcarbamazine citrate.

(*Am J Dis Child* 134:845-847, 1980)

Visceral larva migrans (VLM) is a syndrome, occurring primarily in young children, that is characterized by chronic hypereosinophilia, hepatomegaly, hyperglobulinemia, and recurrent transient pulmonary infiltrates.[1] The cause of VLM syndrome appears to be the ingestion of nematode ova and larvae of *Toxocara canis* or *T cati*.[2] Visceral migration of the larvae, which are unable to mature in the human host, is thought to lead to hypersensitivity reactions induced by the foreign proteins. Many children have elevated isohemagglutinin titers and increases in IgE.[3] Intradermal skin tests with *Toxocara* antigen and various serologic tests[2,4] have been unreliable, owing to cross reactions with *Ascaris* and other parasitic antigens. Definitive diagnosis depends on finding larvae in liver or other tissue biopsy specimens.

We have studied a child with typical VLM syndrome who demonstrated a marked mitogenic response to *Toxocara* antigen but not to *Ascaris* antigen. In addition, a chemotactic abnormality of her granulocytes was found. Despite this chemotactic defect, she had no evidence of bacterial infections. After treatment of the VLM syndrome, partial correction of the abnormal chemotaxis was documented.

REPORT OF A CASE

A 3-year-old girl was seen in May 1974 with a temperature of 38.3 °C (101 °F) and pulmonary infiltrates. The WBC count was 22,500 cu/mm, with 59% eosinophils, and the IgE level was 6,410 IU/mL (normal, under 300 IU/mL). The *Toxocara* titers were 1:512 (indirect hemagglutination) and 1:20 (bentonite flocculation); *Ascaris* titers were 1:128 (indirect hemagglutination) and 1:10 (bentonite flocculation). The fever and pulmonary infiltrates cleared spontaneously. There was no family history of recurrent infections or allergies. The patient reportedly had been seen four months earlier with a similar illness. She played outside frequently, but no pica was observed. The family had no pets, but there were numerous dogs and cats in the neighborhood. In February 1975, she was seen for a viral-like illness consisting of malaise, fever, nausea, and vomiting. The WBC count was 11,100/cu mm, with 44% eosinophils. Findings from chest examination were normal, and no hepatosplenomegaly or lymphadenopathy was detected. Skin test results showed positive mumps (+ 12-mm induration) negative purified protein derivative, and negative streptokinase-streptodornase. Quantitation of T and B cells revealed 65% E-rosette-positive and 23% surface immunoglobulin-positive lymphocytes, respectively. Levels of transaminase, serum bilirubin, and alkaline phosphatase were normal. Immunoglobulin levels were as follows: IgG, 2,000 mg/dL (normal, 620 to 1,400 mg/dL); IgE, 17,790 IU/mL (normal, 0 to 300 IU/mL); IgA, 70 mg/dL (normal, 46 to 418 mg/dL); IgM, 144 mg/dL (normal, 70 to 384 mg/dL).

Additional values included total protein, 7.4 g/dL; albumin, 4.2 g/dL; α_1-globulin, 0.2 g/dL; α_2-globulin, 0.8 g/dL; β-globulin, 0.7 g/dL; γ-globulin, 1.5 g/dL. Blood type was 0. Isohemagglutinin (saline) titers were as

Reprint requests to Department of Pediatrics, University of Minnesota Health Sciences Center, Box 228 Mayo, Minneapolis, MN 55455 (Dr Coccia).

follows: anti-A, 1:4,096; anti-B 1:1,024. The C4 level was 19 mg/dL (normal, 14 to 51 mg/dL); the C3 level was 197 mg/dL (normal, 120 to 185 mg/dL). The illness resolved spontaneously.

In July 1975 *Toxocara* and *Ascaris* titers were negative. The WBC count at that time was 7,400/cu mm, with 33% eosinophils. On Feb 20, 1976, the WBC count was 5,800/cu mm, with 57% eosinophils, and the IgE level was 1,324 IU/mL. Treatment with diethylcarbamazine citrate, 3 mg/kg for 30 days, was begun at that time. In April 1976, the WBC count was 5,600/cu mm, with 9% eosinophils. Since that time, the patient has remained well without recurrence of any symptoms. Repeated WBC and differential cell counts have been normal. Repeated titers in January and April 1977 revealed *Toxocara* titers of 1:64 (indirect hemagglutination) and 1:5 (bentonite flocculation); *Ascaris* titers were undetectable; and IgE titers were 476 and 334 IU/mL, respectively.

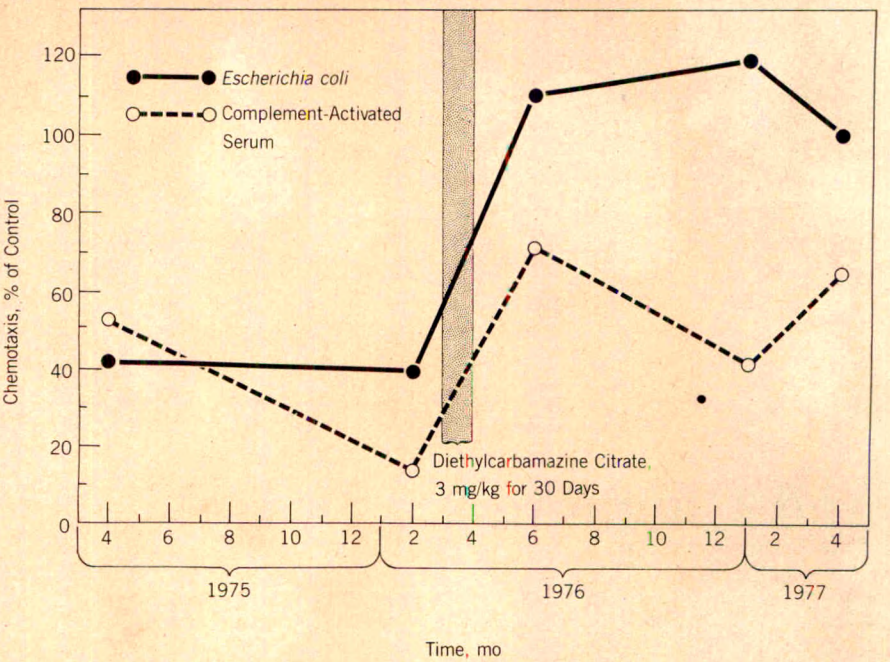
MATERIALS AND METHODS

Chemotaxis was measured by a modification of the Boyden method.[5] Patient and control granulocytes were obtained by dextran sedimentation of heparinized blood. Chemoattractants were filtrates of supernatants from pure cultures of *Escherichia coli* and human control sera in which complement was activated by incubation with zymosan for 30 minutes at 37 °C. Granulocytes and chemoattractants were incubated in chambers separated by 3-μm polycarbonate filters (Millipore) for two hours at 37 °C. Granulocyte suspensions were adjusted to ensure that equal numbers of neutrophils were applied to the filters in all assays. A chemotactic index was derived by dividing the number of neutrophils migrating completely through the filter by the number of neutrophils applied.[6] All assays were done in triplicate.

Lymphocyte transformation assays were performed in triplicate on Ficoll hypaque-separated mononuclear cells obtained from the patient and normal volunteers. Lymphocyte cultures were incubated for 72 hours at 37 °C with dilutions of standard solutions of phytohemagglutinin (PHA), *Toxocara* antigen (0.38 mg of nitrogen per milliliter), *Ascaris* antigen (0.75 mg of nitrogen per milliliter), or no stimulant. Mitogenic response was measured by tritiated thymidine incorporation by scintillation counting.

RESULTS

The results of chemotaxis of patient and control leukocytes to *E coli* filtrates and zymosan-activated sera are shown in the Figure. Prior to treatment with diethylcarbamazine, chemotaxis of the patient's neutrophils to *E coli* or zymosan-activated sera was markedly abnormal compared with normal age-matched control subjects. Following treatment, chemotaxis to *E coli* filtrates became normal. In contrast, chemotaxis to zymosan-activated sera remained abnormal. The patient's serum generated normal chemotactic activity for control neutrophils when exposed to zymosan both before and after diethylcarbamazine therapy.



Chemotactic response of patient neutrophils to *Escherichia coli* filtrates or zymosan-activated normal sera as source of complement expressed as percent of patient chemotactic index compared with control chemotactic index. Multiple same-day control samples gave chemotactic indices within ± 10% of each other on all occasions.

Mitogenic Response to *Toxocara* Antigen

			Ascaris			*Toxocara*		
	Unstimulated	1:100 PHA	25 μg	50 μg	75 μg	19 μg	38 μg	76 μg
Patient, cpm	1,666	138,621	ND*	2,223	828	578,283	592,904	767
Control, cpm	1,951	109,246	1,166	1,418	1,713	ND	998	640

*ND indicates not done.

In the Table, it can be seen that *Toxocara* antigen in concentrations of 19 μg and 38 μg per culture caused a marked mitogenic response in the patient's lymphocytes but none in control subjects. Seventy-six micrograms of *Toxocara* antigen per culture showed no mitogenic response in either patient or control lymphocytes. This concentration may have been toxic to the lymphocytes. *Ascaris* antigen in three different concentrations failed to elicit a mitogenic response in patient or control lymphocytes. The patient and control lymphocytes responded normally to PHA.

COMMENT

This patient demonstrated the typical features of the VLM syndrome—hypereosinophilia, hyperglobulinemia, recurrent pulmonary infiltrates, and elevated isohemagglutinin titers. She also demonstrated markedly elevated levels of IgE, a marked mitogenic response to *Toxocara* antigen, and impaired chemotaxis. Despite abnor-

mal chemotaxis, she had no increased propensity to bacterial infection. The chemotactic abnormality to *E coli* filtrates reversed following treatment of VLM. Concurrently, IgE decreased to near-normal levels and the absolute number of eosinophils became normal. In contrast, chemotaxis to zymosan-activated sera remained abnormal.

Recent investigations have demonstrated a selective in vitro chemotactic defect, which may be elicited by preincubation of normal granulocytes with activated sera as a complement source, while chemotaxis to bacterial chemotaxins remains normal.[7,8] These observations are consistent with the possibility that separate receptors for activated complement and bacterial chemotaxins are present on granulocytes. We believe that our patient may demonstrate this phenomenon. The observation that chemotaxis to *E coli* filtrates returned to normal following treatment but chemotaxis to activated complement remained abnormal suggests that some residual in vivo deactivation of granulocytes to activated complement chemotaxins may remain. In support of this hypothesis, titers to VLM decreased but remained positive, and IgE levels decreased markedly but are still slightly elevated.

The role of IgE as a possible mediator of impaired chemotaxis is unknown.[9] Patients with elevated IgE levels, eosinophilia, recurrent bacterial infections, abnormal cellular immunity, and chemotactic defects have been described.[6,10] While our patient had marked elevation in IgE levels, eosinophilia, and chemotactic defects, she had no increased susceptibility to bacterial infection. Preliminary studies demonstrated that *Toxocara* and *Ascaris* antigens generated chemotactic activity in both the patient's and control sera, but scarce supplies of antigen precluded conclusive studies. Further studies of chemotaxis in patients with VLM syndrome are necessary to confirm our findings.

The definitive diagnosis of VLM syndrome requires the finding of larvae in tissue sections. In an attempt to avoid invasive techniques, various serologic tests[3,4] and intradermal skin tests have been developed. These techniques have lacked both sensitivity and selectivity. Cross-reaction with other parasites, especially *Ascaris*, is the most common problem. The finding of a marked mitogenic response of our patient's lumphocytes to *Toxocara* antigen, but not to *Ascaris* antigen, suggests a promising technique for diagnosing the VLM syndrome. The differentiation of various parasitic infections in patients with hypereosinophilia on the basis of in vitro mitogenic responses may be possible when samples of pure helminth antigens become available.

This study was supported in part by the Education and Research Fund of United Hospitals, Miller Division.

Kenneth Walls, MD, Center for Disease Control, Atlanta, supplied the *Toxocara* and *Ascaris* antigens, and Philip Craddock, MD, University of Minnesota, provided technical assistance in the chemotaxis studies.

Partial Trisomy 9q due to Maternal 9/17 Translocation

Salim F. Aftimos, MD; Joe J. Hoo, MD; Malcolm I. Parslow

• A patient with partial trisomy 9q due to maternal 9/17 translocation was studied and compared with four previously reported cases. The similarity of their clinical features allowed us to delineate a distinct clinical syndrome, which is characterized by psychomotor retardation, dolichocephaly, beaked nose, deep-seated eyes, and long fingers and toes. There is an overlap between some of the features of this syndrome and those of trisomy 9.

(*Am J Dis Child* 134:848-850, 1980)

Trisomy for the distal part of the long arm of chromosome 9 (partial trisomy 9q) has been previously reported in four patients.[1-3] We have studied a fifth patient with this disorder.

REPORT OF A CASE

The patient was born to a 36-year-old gravida 5, para 3, abortus 1 mother at term. There were no antenatal problems, except for two episodes of urinary tract infections. Labor was induced because of decreasing levels of urinary estriols. Fetal distress was noted during labor, with episodes of tachycardia, bradycardia, and meconium staining of the amniotic fluid. The Apgar scores were 4 and 7 at 1 and 5 minutes of life, respectively. The birth weight was 1,810 g, the birth length was 45.5 cm, and the head circumference was 33 cm.

Examination demonstrated several dysmorphic features, which prompted a karyotype analysis. The baby fed poorly and failed to thrive. She was able to follow objects by 2 months of age, but at age 5½ months she did not smile or vocalize. She was not able to lift her head or roll over. Examination at 5½ months of age (Fig 1 through 3) revealed the following values: weight, 4.2 kg; length 60 cm; and head circumference, 42.2 cm.

There was obvious dolichocephaly. The nose was long, fleshy, and slightly beaked, with hypoplastic alae nasae. The eyes were deep-seated. The mouth was small, well designed, and triangular, and there was a narrow, high-arched palate. The chin was small and receding. The ears were relatively large and square, with abnormal folding of the tragus. The neck was short, with redundant skin folds posteriorly. The trunk was asymmetric, the right side being more prominent, and the right nipple was larger than the left.

There were bilateral sacral dimples, as well as elbow dimples. The extremities were thin, and the fingers and toes were unusually long and thin. The fingers were held in flexion, and were clutched over the thumb. There was an extra volar crease on both index fingers at the level of the middle phalanx. Dermatoglyphics were unremarkable. There was nonpitting edema of the dorsum of the feet. The clitoris and labia minora were hypoplastic. There was severe limitation to hip abduction, and some limitation to knee extension.

She had a weak, hoarse cry. The tone was poor. She had stereotyped writhing movements of the arms and legs in an avoidance manner.

A roentgenogram showed the long bones to be unusually long and slender. There were 13 pairs of ribs. The cranial tables were thin, with discrete cortical margins and minimal diploë. The EEG and ECG were normal.

Fig 1.—Full view of patient with trisomy 9q, demonstrating facies, dolichocephaly, slender extremities, and long fingers and toes.

Reprints not available.

Fig 2.—Facies of patient with trisomy 9q. Note long fleshy nose, well-designed triangular mouth, and relatively large ears.

Fig 3.—Hand of patient with trisomy 9q, showing long fingers flexed and clutched over thumb.

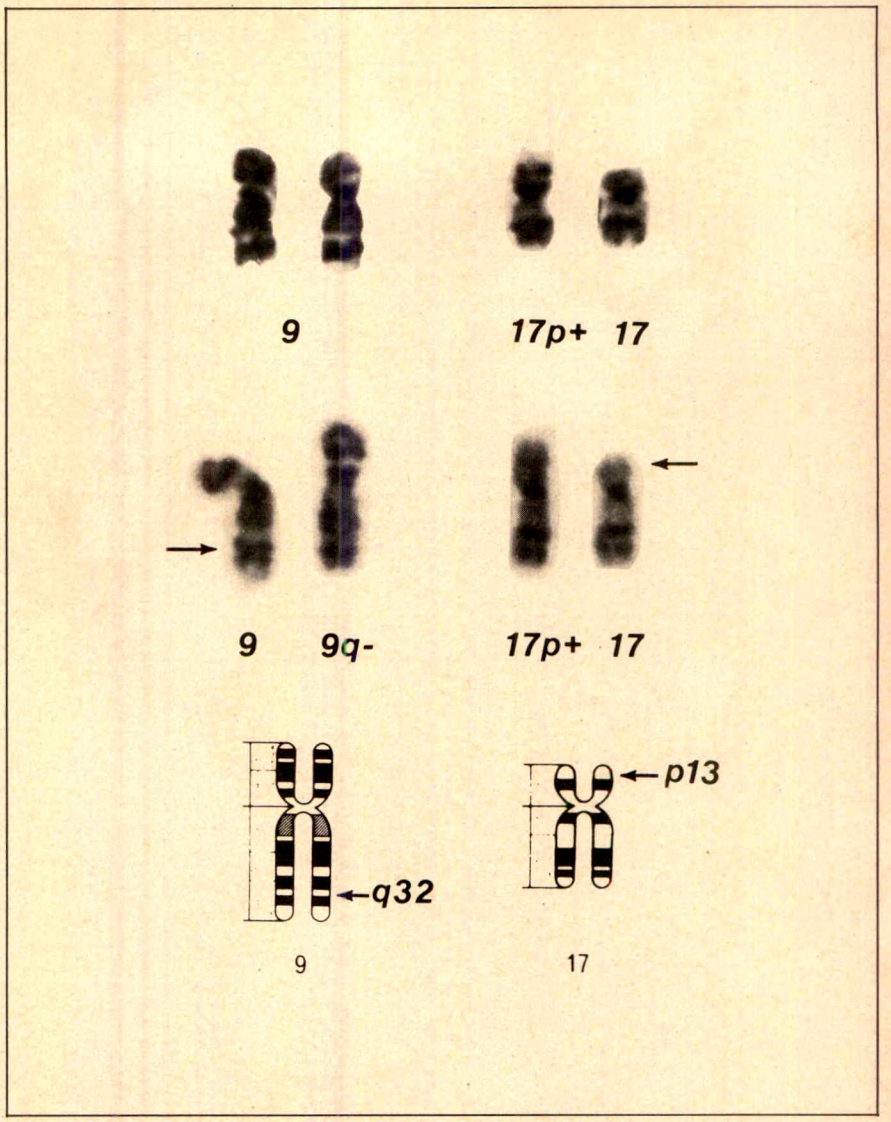

Fig 4.—Partial karyotypes showing pairs 9 and 17 (DNA replication banding) from the patient with trisomy 9q32→qter, 46,XX,der(17), t(9;17) (q32;p13)MAT (top), mother with balanced 9/17 translocation, 46,XX,t(9;17) (arrows show breakpoints in relation to normal chromosome of pair) (middle), and illustration of breakpoints (bottom). Because chromosome pictures are from DNA replication-banded preparations, banding patterns are similar, but not identical, to those obtained after standard Giemsa banding.[6] In particular, proximal region of long arm of chromosome 9 shows dark banding not seen in Giemsa-banded preparation. Pattern on rest of chromosome 9 long arm is same as that obtained after Giemsa banding.

Chromosome preparations were made from lymphocyte cultures grown in the presence of 10 μg/mL of 5-bromodeoxyuridine and pulsed with thymidine for the last six hours before harvesting. These were then stained with DNA-specific fluorescent stain 33258 (Hoechst), exposed to sunlight, incubated in a solution of 0.3M sodium chloride and 0.03M trisodium citrate at 60 °C and stained with Giemsa stain to produce DNA-replication bands.[4,5]

Analysis of such preparations from the patient demonstrated a 46,XX,17p+ karyotype (Fig 4). The abnormal chromosome 17 was inherited from her mother, who was found to carry a balanced translocation t(9;17) (q32;p13) (Fig 4). The patient is therefore trisomic for the region 9q32→9qter.

COMMENT

Several cases of trisomy for the short arm of chromosome 9 (trisomy 9p) have allowed the delineation of a specific chromosomal syndrome.[7,8] The main features of this syndrome include mental retardation, microcephaly, prominent forehead, hypertelorism, enophthalmus, prominent nose, hypoplastic phalanges and nails, clinodactyly, absence of the C triradius, and simian creases. A number of cases have been described of either complete trisomy 9 or trisomy 9 involving the short arm and a variable length of the proximal portion of the long arm.[9-13] The clinical features included most of those of 9p trisomy, with additional features that were variable, depending on the length of

Clinical Features of Partial Trisomy 9q in Five Patients

the segment of the long arm involved in the trisomy. The most important additional features included cranial suture abnormalities, urogenital anomalies, congenital heart malformations, articular malformations, failure to thrive, and early death.

Four patients with trisomy that affected only the distal portion of the long arm of chromosome 9 (partial trisomy 9q) have been reported with comparable features strikingly similar to those described in the present case. The characteristic features are summarized in the Table. Most striking among those are severe psychomotor retardation, craniofacial dysmorphic features, and long fingers and toes. An important negative finding is the lack of dermatoglyphic abnormalities.

Some features of patients with partial trisomy 9q, such as low birth weight and failure to thrive, overlap with those of trisomy 9. Furthermore, limitation of joint movements in three cases, the hypoplastic external genitalia in two cases, and the congenital heart disease in one case, have been described in some of the patients with trisomy 9. In spite of the described similarities, the overall appearance of those patients with partial trisomy 9q permits them to be identified as having a separate syndrome with a characteristic phenotype.

The clinical features of this syndrome will be better delineated as more cases are described. To our knowledge, this is the first case reported in a pediatrics journal, and it is hoped that it will alert pediatricians to this distinct chromosomal syndrome.

Acquired Bile Duct Stricture in Childhood Related to Blunt Trauma

Report of a Case and Review of the Literature

Ross S. Kendall, MD; Paul R. Chapoy, MD; Ronald W. Busuttil, MD, PhD; Marvin Kolodny, MD; Marvin E. Ament, MD

• A 13-year-old boy had obstructive jaundice following several episodes of blunt abdominal trauma. At surgery, a stricture of the common bile duct, for which no other cause could be found, was identified and corrected. We describe our approach to the problem of obstructive jaundice in childhood. In most cases, the application of ultrasonography or computerized tomography and appropriate transhepatic cholangiography can yield a presumptive diagnosis before surgical exploration.

(*Am J Dis Child* 134:851-854, 1980)

Blunt abdominal trauma resulting from assault or automobile accidents poses an increasingly common dilemma to many surgeons. Patients who had suffered massive injuries and shock are usually surgically explored, yet inadvertent injury without immediate signs and symptoms can manifest as late unrecognized sequelae. We recently encountered an uncommon case of obstructive jaundice in childhood, probably due to blunt injury to the common bile duct. Physicians who care for children should be aware that mild, blunt abdominal trauma, with injury to the common bile duct, may be a cause of obstructive jaundice after infancy.

REPORT OF A CASE

On Jan 29, 1979, a 13-year-old boy was transferred from another hospital with a ten-day history of epigastric abdominal pain, nausea, nonbilious vomiting, acholic stools, dark urine, and jaundice. The pain was described as intermittent, crampy, lasting one to two hours, and radiating to the back; it was unrelated to meals, position, or exercise. A history of fever, diarrhea, constipation, melena, rectal bleeding, and hematemesis was denied.

The patient had been well until August 1978, when he experienced similar pain, without jaundice or vomiting, for one month subsequent to several episodes of blunt abdominal trauma. A helmet injury to the upper part of the abdomen had sent him to the sidelines in a football game. The following day, a football hitting the abdomen reproduced excruciating pain. He continued to experience abdominal discomfort thereafter, and lost 5.5 kg, although he did not relate his symptoms to his football trauma. He experienced no change in stool habits. An upper gastrointestinal (GI) tract x-ray series and endoscopy disclosed no pathologic features. After one month of symptoms, he remained asymptomatic from September 1978 to January 1979. A family history of cholelithiasis in the mother, peptic ulcer disease in one grandmother, and a fatal "strangulation of a Meckel's diverticulum" in a sibling was reported.

Our physical examination in January 1979 revealed an obese mildly icteric adolescent in no acute distress. His weight was 60.4 kg and height was 160 cm. Blood pressure was 130/85 mm Hg, pulse rate was 95 beats per minute, respirations were 26/min, and temperature was 37 °C. His stools were pale and without occult blood. Urine was dark and tested positive for bile. There were no physical stigmas of chronic liver disease. He had diffuse right upper quadrant and epigastric tenderness, with marked guarding and no rebound pain. Bowel sounds were diminished. There were no palpable masses or organomegaly, and liver span measured 11 cm by percussion. No bruits were heard over the abdomen. Laboratory values included the following: total serum bilirubin/direct fraction, 5.4 mg/dL/4.5 mg/dL (normal, 1.0 mg/dL); serum alkaline phosphatase, 590 to 735 IU/L (normal, 10 to 45 IU/L); SGOT, 279 IU/L (normal, 6 to 36 IU/L); SGPT, 945 IU/L (normal, 10 to 45 IU/L); 5′ nucleotidase, 20.9 mu/mL (normal, 15 mu/mL); and antistreptolysin O titer, 500 Todd units (normal, 120 Todd units). Normal values were obtained for serum amylase, amylase-creatinine clearance ratio, total serum proteins, albumin, electrolytes, BUN, creatinine, cholesterol, triglycerides, blood hemo-

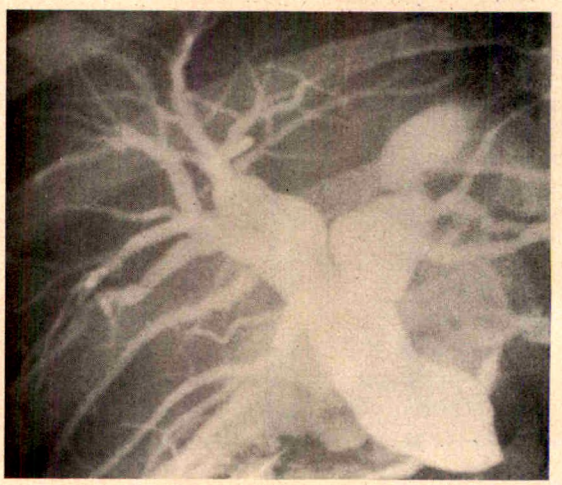

Fig 4.—Transhepatic cholangiogram showing common bile duct stricture.

globin, hematocrit, WBC count and differential cell count, and prothrombin time.

An abdominal ultrasound examination demonstrated dilated bile ducts ("shotgun sign")[1] and a dilated cystic structure at the level of the common bile duct (Fig 1 and 2). The liver appeared normal; pancreatic echoes were obscured by bowel gas, and the gallbladder was not identified. Abdominal computerized tomography (CT) confirmed dilation of the bile duct (Fig 3). A transhepatic cholangiogram revealed total extrahepatic obstruction of the biliary tract at the middle third of the common bile duct, with dilation proximally to a diameter of 1.5 to 2.0 cm (Fig 4).

Exploratory laparotomy was performed four days after admission. At surgery, a fibrous mass encasing a strictured distal common bile duct was identified. After ruling out malignancy (by frozen section), a Roux-en-Y diversion was performed with resection of the involved common duct and fibrous mass, cholecystectomy, choledochojejunostomy, jejunojejunostomy, and needle biopsy of the liver. The gallbladder was contracted with gross and microscopic evidence of chronic inflammation; there were no gallstones. The common duct was strictured and there was evidence of chronic inflammation and extravasation of bile into surrounding fibrous tissue (Fig 5 and 6). The liver showed minimal perportal

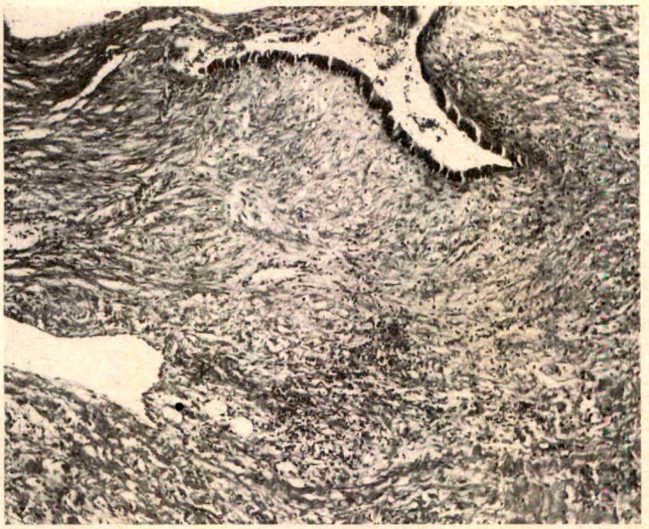

Fig 5.—Common bile duct shows chronic inflammation and fibrosis above stricture (hematoxylin-eosin, original magnification ×64).

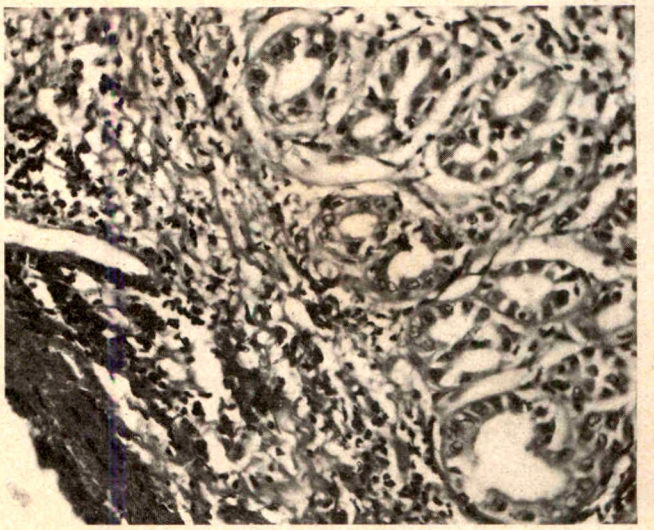

Fig 6.—Common bile duct shows proliferating bile duct structures. There is mild inflammation and fibrosis at site of stricture (hematoxylin-eosin, original magnification ×205).

inflammation and bile duct proliferation. There was no evidence of a malignant neoplasm in tissue submitted from the gallbladder, liver, common duct, duodenum, or sentinel lymph nodes. There were no microabscesses in the wall of the common duct to suggest cholangitis, nor were there hemosiderin-laden macrophages to suggest resolved hematoma. No extravasated bile lakes were seen outside the duct lumen.

The patient made a rapid recovery. Bile obtained at transhepatic cholangiography and surgery proved to be sterile. Patency of the biliary tree was demonstrated radiographically one week after operation. Liver function has since returned to normal and the patient remains clinically well 11 months after hospital discharge.

COMMENT

Isolated blunt injury to the extrahepatic ducts occurs rarely in children and adults. In one adult series[2] of 43 patients with nonsurgical trauma to the extrahepatic bile ducts, only six had suffered injury to other major organs. Such figures are representative of other large studies of the problem.[2-4] Among the ten cases reported by Fletcher et al,[4] only three involved children and all were toddlers. A recent review of the literature[5] uncovered only 33 cases of nonpenetrating injury to the bile ducts in children since 1916, most of which were part of massive multiple trauma patterns secondary to battering or automobile accidents. Moreover, in only six of these was the injury to the common bile duct isolated and incomplete enough to manifest with long-delayed sequelae, namely, biliary obstruction. The site of injury was usually at the pancreatic-duodenal junction. The other site of ductal injury was at the bifurcation of the hepatic duct or the origin of the left hepatic duct, and involved hepatic trauma as well. It is known that shearing forces cause tearing at points of maximum fixation, occurring in the biliary tree at the point of exit from the porta hepatis and entry into the pancreas. The common bile duct is shorter and more fixed than the accompanying artery or vein, so that it can be individually injured. One case of blunt injury to the midcommon duct in a 19-month-old child has been reported.[6]

Bile duct strictures causing obstructive jaundice are very rarely seen in pediatric patients. Cholestatic jaundice may be classified as intrahepatic or extrahepatic. After infancy, in the United States and Europe the predominant sources of extrahepatic obstructive jaundice are (1) obstruction to the intrapancreatic portion of the common bile duct from inflammation (pancreatitis) or pancreatic pseudocyst (traumatic or postinflammatory), (2) choledochal cyst or other congenital anomalies, (3) cholelithiasis, and (4) cholangitis. In underdeveloped countries, parasites such as *Ascaris*, *Clinorcis sinenses*, *Fasciola hepatica*, and, occasionally, *Echinococcus* produce extrahepatic biliary obstruction. Strictures, which are rare, can be congenital, malignant, or inflammatory in origin. Inflammatory strictures can be secondary to cholangitis (infection, "pancreatic reflux") or trauma.

Although many authors state that stricture of the common bile duct usually follows surgical complications of cholecystectomy,[7-11] the rate of stricture following such surgery is less than 1%. In Warren and Jefferson's review of 987 patients with bile stricture seen during a 25-year period at the Lahey Clinic, 97% occurred after surgery.[10] Of the 29 cases (3%) in which surgery could not be implicated, 15 were inflammatory (ie, secondary to documented cholangitis), five were congenital, seven were secondary to gallstones, and only two developed from blunt external trauma.

Proof of a cause-and-effect relationship between the trauma and stricture was, as in our patient, circumstantial. In cases of complete transection with bile peritonitis,[12] the relationship is clear. However, in our case, congenital and infectious causes must be eliminated by the history (onset in adolescence subsequent to lack of fever, without recurrent obstruction after 11 months), findings of laboratory tests (sterile bile cultures), and the pathologic features

(absence of microabscesses in the wall of the common duct, absence of gallstones). Several authors have recently argued that a continuum of bile duct injury, from stricture or perforatior to choledochal cyst, may stem from pancreatic reflux into a congenitally deformed pancreaticobiliary junction.[13,14] In the past, spontaneous perforation of bile ducts, a well-documented occurrence only in the neonate,[15] has been ascribed to increased intraluminal pressure on areas of the duct weakened by a congenital anomaly or prenatal infarction of the wall. Whether congenital bile strictures are secondary to sublethal variations of these complications or result from failure to recanalize during embryogenesis is unknown. Our patient is beyond the age when a congenital bile duct stricture could develop.

We used the accepted radiologic approaches used in adults to examine our patient: ultrasonography, CT scan, and percutaneous transhepatic cholangiography. Many authors have debated the advantages and disadvantages of ultrasonography vs CT scan in the investigation of possible obstructive jaundice and delineation of the biliary tree.[1,16-19] Both studies demonstrated the problem clearly in our patient. There are no good published series on the use of ultrasonography vs CT in the diagnosis of childhood jaundice. Ultrasound is the preferred scanning method over CT scan in our facility because of lower costs and a skilled ultrasonography department. The efficacy and safety of transhepatic cholangiography in defining biliary obstruction have been well shown in adults[20,21]; however, no large series has been published on its use in children. It has been successfully used in infants,[22] and we are now employing it without difficulty in most children in whom the cause of obstructive jaundice has not clearly been demonstrated by noninvasive means.

The surgical approach to nonmalignant disruption or obstruction of the distal common bile duct has been well reviewed by several authors.[10,23-26] Several approaches, including direct anastomosis over a T-tube stint, choledochojejunostomy, Roux-Y cholecystojejunostomy, Roux-Y choledochojejunostomy, and choledochogastrostomy, are used. Most surgeons now perform the repair procedure used in our patient, a Roux-Y choledochojejunostomy. A discussion of the various procedures is beyond the scope of this presentation.

CONCLUSION

This case probably represents a distinctly unusual injury resulting from blunt abdominal trauma in childhood. To our knowledge, it is only the seventh such case reported in the pediatric age group. Although it is a rare cause of cholestatic jaundice in childhood, a history of trauma should be sought in puzzling cases of biliary obstruction. This case demonstrates that diagnostic tools available for the investigation of obstructive jaundice in adult patients are also valuable in pediatric diagnosis.

Intracranial Hemorrhage in the Premature

Its Predictive Features and Outcome

Niki Kosmetatos, MD; Colleen Dinter, MD; Margaret L. Williams, MD; Herbert Lourie, MD; Alfred S. Berne, MD

• **Sixty-four infants with birth weights of 500 to 1,500 g were studied to determine the incidence and outcome of intracranial hemorrhage. Thirty-seven (58%) had hemorrhage and of these 60% died. Of the survivors, progressive hydrocephalus requiring treatment developed in only two infants. Serial computerized tomographic scans with measurement of ventricular-brain width ratios were found to be useful in objectively evaluating hydrocephalus. Review of perinatal data showed no association of maternal or obstetrical factors with neonatal hemorrhage but the infants who had intracranial bleeding showed a high incidence of low Apgar scores, respiratory distress syndrome, acidosis, hypoxia, apnea, hypotension, seizures, and requirement for respiratory support. Multiple regression analysis of potentially causative factors assigned importance to low gestational age, respiratory distress syndrome, birth asphyxia (low Apgar score), and vaginal delivery.**

(*Am J Dis Child* 134:855-859, 1980)

With progressive improvement in respiratory support of the preterm infant, an increasingly recognized cause of death has been intracranial hemorrhage.[1-5] Numerous studies on the cause and timing of such hemorrhages and their relationship to the respiratory distress syndrome, hypoxia, hyperosmolarity, and clotting deficits have been undertaken.[6-11]

Until recently, the antemortem diagnosis of intracranial hemorrhage has been made by indirect means, such as evaluation of clinical signs and examination of spinal fluid, which has made study of incidence and interpretation of associated factors difficult and possibly inaccurate. The advent of computerized axial tomography (CT) offers for the first time the opportunity to make positive antemortem diagnoses and to follow the natural history of this disease.[12-16] Computerized tomographic scanning also allows the clinician to observe the development of hydrocephalus and to evaluate objectively the efficiency of varying therapeutic regimens.

The following report of experience with intracranial hemorrhage measures incidence, describes clinical course, and attempts to delineate the antecedents of hemorrhage in a high-risk population—the infant who weighs less than 1,500 g at birth.

MATERIALS AND METHODS

All infants of birth weight 1,500 g or less, either inborn or transported, admitted to the Special Care Nursery at Crouse Irving Memorial Hospital in Syracuse, NY, from Feb 1, 1978 through Sept 31, 1978 were entered into the study. Infants clinically suspected of having had an intracranial hemorrhage were scanned by CT as soon as the clinical condition permitted; all other infants were scanned at 7 to 10 days of age. Surviving infants in whom hemorrhage had been demonstrated were followed up weekly for four weeks by CT scanning to observe for progressive ventricular dilation. If an infant died prior to CT scanning, every attempt was made to obtain an autopsy or to perform intraventricular taps to establish the diagnosis of intraventricular hemorrhage.

Data collected on each pregnancy included maternal age, parity, underlying illness, medications, complications of pregnancy, and expected date of confinement. Delivery history as to the time of rupture of membranes, duration of labor, presence of fetal distress, mode of delivery, presentation, anesthesia, and Apgar scores was ascertained where possible and resuscitative measures were recorded. Weight, height, and head circumference were entered on standard growth charts. Physical, neurological, and Dubowitz examinations were performed on the infants. Vital signs, including blood pressure, daily weights, daily fluid intake, weekly head circumference, blood glucose determinations with glucose oxidase paper strips (Dextrostix), as well as sex, race, and birth order were recorded for all infants. Maternal menstrual history, Dubowitz examination results, and intrauterine growth data were used to estimate gestational age.

Reprint requests to Perinatal Center, Good Samaritan Hospital, Cincinnati, OH 45220 (Dr Kosmetatos).

Assays of serum sodium, potassium, calcium, bilirubin, capillary or venous hemoglobin, arterial or capillary blood pH, P_{CO_2}, and P_{O_2}, and spinal fluid were obtained when indicated. Respiratory support information was recorded.

The CT scanning was performed in the Department of Radiology with the use of a head scanner. A one-minute scan time was used. Sedation was not necessary and thermal and respiratory support and cardiac monitoring were provided as necessary. One of us (A.S.B.), a radiologist, reviewed all CT scans.

Once the presence of hemorrhage was established, an attempt was made to determine extent and location. Hemorrhages were divided into four groups based on location: subarachnoid only, subependymal, intraventricular (IVH), and parenchymal plus IVH. As an objective measurement of ventricular dilation, a ventricular width-brain width (V/B) ratio was determined in the plane of the head of the caudate nucleus. After reviewing CT scans in the infants who had no hemorrhage, a V/B ratio of less than or equal to 0.2 was considered normal. Any ratio greater than 0.2 was considered to represent ventricular dilation. This measurement was also used to follow the progression of dilation on serial CT scans.

The presence of respiratory distress syndrome was determined by clinical and laboratory evidence consistent with the diagnosis in the presence of a compatible chest roentgenogram. Other causes of respiratory distress, such as transient tachypnea of the newborn, pneumonia, and aspirations, were considered as a separate category. All roentgenograms were reviewed without knowledge of the clinical diagnosis or the presence of hemorrhage. Arterial or capillary blood samples were obtained in 57 of 64 babies. Hypercarbia was defined as a P_{CO_2} above 50 mm Hg, acidosis as a pH less than 7.20, and hypoxia as a P_{aO_2} of less than 50 mm Hg, a capillary P_{O_2} of less than 35 mm Hg, or clinical cyanosis. Only those determinations made in the first 48 hours of life were included in the analysis as insufficient data are available on well infants and infants who died to allow comparison with the hemorrhage group after this period.

In the evaluation of apnea, episodes were considered as present when the infant's respiratory monitor was triggered after a 15-s delay and the infant was found to be without respiratory effort. Only episodes that occurred in the first 48 hours of life and required either stimulation or other intervention were considered. Apnea developed in only one infant in the first week of life after the first 48 hours. Apneic episodes developed in this infant on day 6 and the infant was diagnosed as having necrotizing enterocolitis. Since this infant did not have an intracranial hemorrhage on CT evaluation and the apnea could be related to another cause, analysis of apnea as a variable was confined to the first 48 hours.

Total intake of all fluids, including blood products, medications and "intravenous flushes" as well as intravenous and oral maintenance was determined for the first and second day of life. Infants were divided into two groups for statistical analysis: those with intakes less than 150 mL/kg/day and those with intakes greater than or equal to 150 mL/kg/day. Hypernatremia was defined as a serum sodium level greater than or equal to 150 mEq/L, hyponatremia as less than or equal to 130 mEq/L. A blood glucose determination with glucose oxidase paper strips in the first 48 hours of life greater than 130 mg/dL was considered hyperglycemia.

Significance of individual observations was computed by Student's t test or χ^2 test with Yates' correction. A stepwise multiple regression analysis was performed on the data relevant to the cause of hemorrhage.

RESULTS

Seventy infants with birth weights between 500 and 1,500 g were entered in the study. Six infants died before any evaluation could be performed, and autopsy permission was denied. These six infants ranged between 510 and 1,330 g (mean, 890 g) and between 23 and 37 weeks' gestation (mean, 27.8 weeks). They did not differ in historical, clinical, or laboratory data from the remainder of the infants and were excluded from further evaluation.

Of the remaining 64 infants, 37 were found to have intracranial hemorrhage, an incidence of 58%. Diagnosis was made at autopsy for seven cases, by postmortem ventricular taps for three, and by CT scan for the remainder. The characteristics of the entire population are given in Table 1. The infants with hemorrhage had significantly lower gestational ages and birth weights than those without hemorrhage, but otherwise the groups were similar.

Table 2 gives the outcome of the two groups with regard to survival, presence of initial ventricular dilation, and subsequent progress of the dilation. Twenty-two of the 37 infants with hemorrhage died, whereas all but two of the 27 infants without hemorrhage survived. Infants with subarachnoid hemorrhage only or subependymal hemorrhage that had not extended to the ventricles had a lower mortality than those with ventricular and parenchymal involvement. Although initial ventricular dilation was seen in 16 of the 27 infants with hemorrhage who had CT scans, progressive hydrocephalus requiring the placement of a shunt developed in only two. The others showed stable or regressing ventricular size by the second to third week on CT evaluation.

Historical, clinical, and laboratory data were analyzed to determine predictors of hemorrhage. No association was demonstrated between hemorrhage and any maternal historical information, complications of pregnancy, fetal presentation, duration of labor, and presence of fetal distress. With respect to the infant, the development of hemorrhage was associated by χ^2 analysis, with low Apgar score, need for ventilation in the delivery room, subsequent development of respiratory distress syndrome, metabolic acidosis, hypoxia, apnea, hypotension, seizures, and requirement of respiratory support, either constant positive airway pressure or ventilator (Table 3). Infants with hemorrhage received

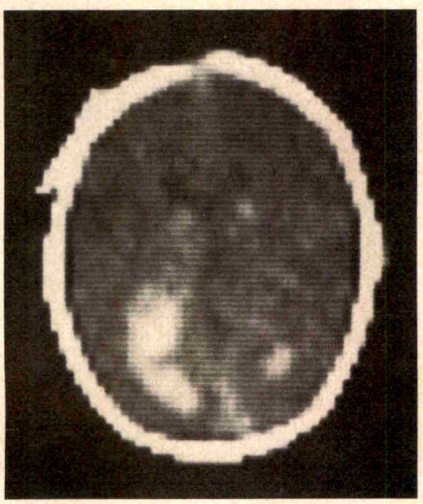

Fig 2.—Same infant four weeks later progressing to hydrocephalus.

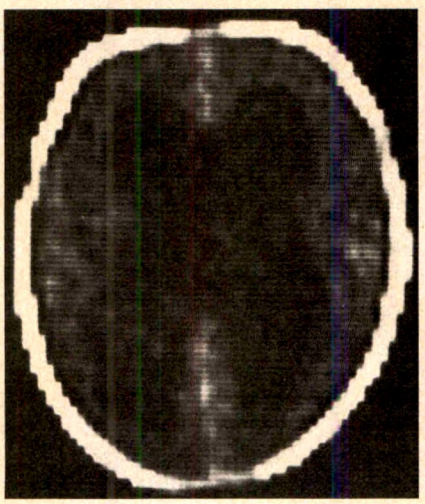

somewhat greater fluid intakes on the first day of life than those with no hemorrhage. No association of intracranial bleeding with hypothermia, hypernatremia, hyponatremia, hypercarbia, or hyperglycemia was noted.

Several of the factors examined have been suggested as possibly causative as well as symptomatic of intracranial hemorrhage. Since the majority are interrelated, a stepwise multiple regression analysis was performed of variables that might have causal importance. The most significant independent contributions to the variability ($P < .001$) were made by low gestational age and presence of the respiratory distress syndrome. Other significant independently related variables ($P < .01$) included low Apgar score (as a measure of intrauterine insult), the presence of respiratory distress from other causes than respiratory distress syndrome, and vaginal delivery as opposed to cesarean section. Seven of 18 infants delivered by cesarean section had intraventricular hemorrhage, compared with 30 of 46 infants delivered vaginally. Acidosis, hypoxia, hypercarbia, and hypotension did not appear to play a role when examined by multiple regression analysis. The difference in results may be due to the interrelation of these factors with respiratory distress syndrome and birth asphyxia. Birthweight, sex, and hypothermia also did not appear to play a role in the development of intracranial hemorrhage on regression analysis.

Seizures developed in 12 infants in the hemorrhage group and none in the nonhemorrhage group. The development of seizures in the low-birthweight sick infant suggested the diagnosis of intracranial hemorrhage clinically. However, the absence of seizures did not exclude the diagnosis since 25 of the 37 infants with hemorrhage had no seizure activity. The 12 infants with seizures had more severe hemorrhages: five had extensive hemorrhages with parenchymal involvement and seven had intraventricular hemorrhages without parenchymal extensions. The absence of seizures, however, did not necessarily indicate milder hemorrhages since 18 of these infants had intraventricular hemorrhages (two with parenchymal involvement). Bulging fontanelles were found in only eight infants with hemorrhages and six of these had seizures. Decreases in hematocrit levels were not useful indicators of hemorrhage since multiple blood drawings and transfusions made interpretation of hematocrit values difficult. Twenty-one of the 37 infants with hemorrhage had no clinical indications and diagnosis was made by CT or at postmortem.

As with diagnosis, only the presence of seizures correlated with the clinical course and site of hemorrhage. Infants with seizures had the most extensive hemorrhages often with parenchymal involvement, and the highest mortality: only one of the 12 survived; progressive hydrocephalus developed in that infant (Fig 1 and 2). By comparison, 14 of the 25 infants without seizures survived. Table 2 gives the survival of infants with hemorrhages based on the location of hemorrhage and initial ventricular dilation.

COMMENT

Intracranial hemorrhage is an important cause of neonatal mortality and morbidity in the low-birth-weight infant. Until recently, the diagnosis was made by postmortem examination or inferred from physical signs, symptoms, and laboratory data. Using these variables, an almost uniformally fatal outcome was assumed. Recent studies indicate that such is not the case and also suggest a higher incidence of neonatal hemorrhage than previously suspected since all hemorrhages do not necessarily result in symptoms.[16-17]

Using CT, Papile et al[16] found an incidence of intracranial hemorrhage of 43% in infants of birth weight less than 1,500 g and demonstrated that 45% of these infants survived the hemorrhage. Even more surprising was their finding that 78% of surviving infants with documented hemorrhage had no clinical findings consistent with intracranial bleeding. This study served to illustrate that the incidence of intracranial hemorrhage when diagnosed by clinical signs alone is probably underestimated, and that prognosis for surviving infants may be better than previously assumed.

Our data support these conclusions. In the present study, the incidence of hemorrhage was 58%; and 40% of these infants survived compared with 92% survival in the nonhemorrhage group. More importantly, the short-term outcome of these infants was remarkably good. All except one infant had no evidence of gross blood by CT scan at nine to ten days after the hemorrhage. Progressive ventricular dilation developed in only two children requiring shunting procedures; in the other children who had initial dilation, ventricular size stabilized or decreased by the end of the month (Fig 3 and 4). This is a lower incidence of hydrocephalus than has previously been reported in surviving infants. Ventricular dilation was more common with extensive intraventrical hemorrhage with or without parenchymal extension as opposed to subependymal or mild hemorrhage. However, as most infants with extensive hemorrhages did not survive, the question of how many infants with such hemorrhages, if surviving, would go on to have progressive ventricular dilation remains unanswered. In only one of the two infants with progressive dilation would the clinical course and site of hemorrhage have been helpful. The other infant had a moderate hemorrhage without parenchymal involvement and mild initial ventricular dilation. It is apparent that a spectrum of disease occurs and in larger series it is possible that correlation of clinical presentation with initial CT evaluation may provide useful objective criteria for predicting outcome.

The V/B ratio was used as an objective measure of ventricular size. An attempt was made to establish criteria of "normality" in infants without hemorrhage, and serial measurements were used to follow the progress of ventricular dilation in individual infants. In view of finding that ventricular size will stabilize or decrease in most infants after hemorrhage, it is important to follow this measurement objectively for a period of time prior to initiating treatment. These data can also serve as a baseline in evaluating the results of varying therapeutic

regimens, such as repeated lumbar puncture,[18-19] glycerol[20] or isosorbide administration,[21] or shunting procedures.

With the improved potential of accurate diagnosis by CT scan, it is now increasingly possible to identify risk factors associated with hemorrhage. Symptoms, such as apnea, hypotension, and acidosis, occur so regularly with intracranial bleeding that their appearance in a small premature infant is very suggestive that hemorrhage may be occurring. Difficulty persists however in distinguishing causal factors from events occurring as a result of the hemorrhage. Regression analysis suggests that many of the associated findings represent related effects of the hemorrhage that do not independently influence the occurrence of the bleeding. Hypotension for example was a frequent concomitant of hemorrhage but did not seem to have an independent causative role, a fact not supportive of the recent suggestion of Lou et al[22] that the impaired autoregulation of cerebral blood flow in distressed newborn infants might allow hypotension to be a factor in the cause of hemorrhage. Analysis of possible causative factors related hemorrhage most strongly to immaturity and to the presence of hyaline membrane disease irrespective of hypoxia. It is possible, however, that the latter association may represent a common causation for the two diseases as opposed to damage to the cerebral circulation resulting from some facet of the pulmonary disease.

Another factor identified as independently important was the mode of delivery. A large number of the infants in whom intracranial bleeding did not develop had been delivered by cesarean section, whereas most of those who had hemorrhage were born vaginally. Passage of the soft head of a premature infant through the birth canal increases the potential for both depression of cerebral blood flow and cerebral trauma. Although the data suggest that cesarean section may offer protection against intracranial hemorrhage, further documentation of this fact should be sought before it is used as a basis for recommendation of surgical delivery for all small premature infants.

The very low-birth-weight infant should be considered at risk for intracranial bleeding that now can be diagnosed by CT scan. However, the as-yet unproved safety in terms of radiation exposure to the retina prompts restriction of its use to only those infants who are at high risk and to the minimum exposure necessary to obtain the information. Until further delineation of the relationship of symptoms to outcome, the infants in whom hemorrhage is identified must continue to be considered at maximum risk for later neurological, developmental, and behavioral problems.

The present study was approved of by the Human Research Review Committee of Crouse Irving Memorial Hospital.

Pregnancy, Delivery, and Neonatal Complications Among Autistic Children

Eva Y. Deykin, DPH, Brian MacMahon, MD

• **An investigation of the prenatal, delivery, and neonatal experience of 145 autistic children matched with 330 unaffected siblings revealed that among the propositi there was a preponderance of first-born children. Obstetrical records, which had been made prior to the diagnosis of autism, indicated that autistic children were more likely than their siblings to have experienced at least one untoward event during their mothers' gestations and deliveries. Similarly, the autistic children had an increased risk of neonatal complications. Despite the significant excess of total reproductive complications in the autistic series, there was no single event or a combination of biologically related complications that could reasonably account for any large number of cases of autism. While it is possible that autism may be the product of several diverse deleterious events experienced in utero, during delivery, or in the early neonatal period, our finding could be a chance occurrence or could signal the presence of an unknown factor responsible both for autism and for a variety of reproductive complications.**

(*Am J Dis Child* 134:860-864, 1980)

The symptomatology and clinical course of autism suggest that physical damage to the brain or nervous system may play a role in the etiology of this disorder.[1-3] High frequencies of electroencephalographic (EEG) abnormalities,[4,5] seizure disorders,[6-8] and cognitive deficiencies[9,10] among autistic children may indicate a nonspecific neurologic involvement. Since a variety of reproductive complications are associated with fetal neurologic impairment, we have examined the role of selected obstetric, delivery, and neonatal difficulties as possible contributors to the development of autism.

As part of a study evaluating a possible association between prenatal or early infancy viral exposure and the subsequent development of autism, a series of 183 autistic children and 355 unaffected siblings was assembled, and prenatal, delivery, and early neonatal medical data obtained.[11] In this report we compare the frequency of prenatal and delivery complications and early medical difficulties for the autistic children and their nonautistic siblings.

SUBJECTS AND METHODS

The Sample

The subjects for this investigation consisted of 145 autistic children and 330 unaffected siblings, a subsample of the larger study.[11] Twenty of the original 183 autistic children were excluded because they had no siblings for comparison. An additional 18 cases belonging to nine individual sibships were excluded from the study because the propositi came from families with more than one autistic child. Sibships with more than one autistic child were excluded because the matched analysis was designed to evaluate the frequency of the selected reproductive complications among the propositi relative to normal siblings within each sibship. Inclusion of sibships with two autistic children would have necessitated the use of the same comparison subjects twice.

Cases were referred to us between June 1975 and January 1977 by 19 agencies in Massachusetts known to evaluate, treat, educate, or care for children with autism or related disorders. The referral sources included psychiatric and neurologic clinics, in-patient psychiatric units, evaluation centers at schools for the retarded, and special day and residential schools. With the exception of two referral sources that were primarily diagnostic and referral centers, all agencies referred children who were currently under their care. The two diagnostic centers referred children evaluated in the preceding 12 months but who were not undergoing diagnostic procedures at the time of the study. To protect confidentiality, the agencies' directors wrote to parents describing the study as an investigation of childhood developmental difficulties. The names of families who expressed a willingness to participate were given to us for further contact.

A subject's inclusion in the study was determined by the history of manifest symptomatology rather than by the diagnosis of autism. Subjects were potentially eligible for study inclusion if by age 6 they had exhibited one or more symptoms in at least one of the three areas described subsequently. Children with manifest impairment in all three areas were classified as totally or classically autistic; those with a history of impairment in only one or two areas were classified as partially autistic. In the total sample of 183 autistic children, 132 (72%) showed impairment in all three areas by age 6; 44 (24%) showed impairment in two of the three areas; and seven (4%) showed impairment in only one area. Among the subsample of 145 children included in this study, 125 (86%) were totally autistic. Because of the small number of children with fewer than three impaired areas, totally and partially autistic subjects were combined.

The 19 participating medical and educational facilities referred children whose clinical record contained a notation of impairment in at least one of the three specified areas. Confirmation of the symptoms was obtained by an interview with the subjects' parents. Only seven subjects who had been referred failed to meet study inclusion criteria either because the onset of symptoms occurred after age 6 or because their symptomatology did not represent any of the three areas of impairment. It seems clear that the referral

sources correctly identified a large proportion of subjects eligible for study inclusion. Unfortunately, we are not able to assess the number of potential study subjects who were not referred.

Symptom Areas

The three general areas that were considered criteria for autism were (1) impaired relatedness to the environment, characterized by (*a*) extreme aloneness, lack of responsiveness to human contact, no interest in people, and apparent emotional self-sufficiency, (*b*) physical withdrawal from people, stiffening when held, pushing people away, and a preference for isolation, (*c*) avoidance of eye to eye contact, and (*d*) treatment of persons as inanimate objects; (2) stereopathy, characterized by (*a*) repetitive acts, play, or behavior, (*b*) insistence on sameness in routine and environment, (*c*) self-stimulation (head banging, compulsive masturbation, repetitive scratching, or picking at skin), (*d*) rigid food preferences and aversions, and (*e*) rote memory; and (3) impaired language development, characterized by (*a*) mutism (no spoken language), (*b*) echolalia (parroting the speech of others, use of third person rather than first person pronouns), (*c*) communicative speech limited to a few words, and (*d*) aberrant inflection.

Data Collection

Data on pregnancy, delivery, and neonatal complications were obtained by interviewing the subjects' mothers and by reviewing all available obstetrical and delivery records. Medical records were found for 118 of the 145 propositi (81%) and for 246 of the 355 unaffected siblings (75%).

To minimize observation bias, a research assistant, who was unaware of which child in the sibship was the propositus, abstracted the medical records. While data have been collected from both sources (medical records and family interview), we have, in this analysis, used only medical record data for the assessment of complications during pregnancy and delivery. However, for events in the early postnatal phase, data from the interviews were used, since the obstetrical records rarely contain information beyond the delivery phase. To evaluate whether the data provided by the subjects' mothers could be considered reasonably accurate and unbiased, we compared the information on pregnancy and delivery difficulties obtained from the mothers with that found in the medical records. In addition, we also determined the proportion of complications reported by the families that were substantiated by the medical records and the proportion of medically reported events confirmed by the maternal interviews, both for propositi and for the comparison group of siblings. Estimates of risk of pregnancy and delivery complications obtained from interview data were very similar to those obtained from medical data only. The proportion of family-reported complications confirmed by medical records and the proportion of record data confirmed by family interviews were comparable for propositi and siblings. The results of these comparisons indicate that family-provided data are consistent with those found in medical records. There was no evidence that the mothers preferentially recalled medical events for either propositus or siblings.

Methods of Analysis

Since the comparison subjects were the unaffected siblings of the propositi, the propositi and the comparison subjects were matched on a variety of genetic and environmental factors. The data were therefore subjected to a matched analysis designed to accommodate propositi with a variable number of comparison subjects.[12] Factors that might confound the association between reproductive complications and autism were controlled for in the analysis.

RESULTS

Among the autistic children there were almost 4.5 times as many males as females (118 vs 27). Among the siblings the number of males and females were roughly equal (163 and 167, respectively).

Birth Order

As shown in Table 1, there was an excess of first-born and a deficit of second-born among the propositi. Table 2 gives the distribution of autistic children by birth order and sibship size. The expected number of autistic children in each birth order was estimated by the Greenwood-Yule method,[13] which presupposes completed sibships. When some sibships are still incomplete, as is the case in this sample, the Greenwood-Yule method will produce an over-representation of propositi in the later birth orders. The data in Table 2, reflecting the observed and expected birth order distribution of autistic cases by sibship size, indicate that the excess of autistic children in the first birth order is evident only in small sibships, whereas the deficit of cases in the second birth order is present in sibships of all sizes. The observed excess of cases in birth orders 5 and above is possibly due to the bias just mentioned and cannot be construed to indicate an excess risk for children who are the youngest of several siblings. The difference between the observed and expected distribution of cases by birth order tested by χ^2 for homogeneity is significant at $P < .001$.

Table 1.—Birth Order of Propositi and Siblings

Birth Order	Propositi		Siblings	
	No.	%	No.	%

Prenatal Complications

Information on eight pregnancy events was obtained from the obstetrical records of 118 autistic children and 246 unaffected siblings. The events of interest were prenatal trauma requiring medical attention (falls, auto collisions, burns, or cuts); nausea with vomiting beyond the first trimester; light bleeding after the first trimester; heavy bleeding at any time; edema (+ + or more); toxemia; physician-attended maternal illness or febrile illness of at least two days' duration; and physician-prescribed drugs, excluding vitamin or iron supplements.

Excepting edema and toxemia, for all other events of interest, there was some elevation of risk for the autistic children. The excess in frequency ranged from a low of 10% for light bleeding after the first trimester to a high of 360% for maternal accidents and for heavy bleeding at any time during pregnancy. The difference in frequency of pregnancy complications between propositi and comparison subjects was significant ($P = .05$) for use of medication; differences between the two groups for other complications were not statistically significant. However, autistic children were significantly more likely than their siblings to have at least one of the listed complications ($P < .05$) (Table 3).

Table 3.—Prenatal Complications Recorded in Obstetrical Records

Complication	No. With Complication		Relative Risks*		95% Confidence Interval for Adjusted Relative Risk
	Propositi (N = 118)	Siblings (N = 246)	Unadjusted	Adjusted for Birth Order

At least one of the above	78	152	1.2	1.5	1.1-2.0

*Maximum likelihood estimates of relative risk.

Labor and Delivery Complications

Eight complications of delivery were investigated. These were emergency cesarian sections, vaginal delivery aided by forceps, malposition of fetus, cord problems (which included both prolapse of cord and wrapping the cord around the child's neck), hemorrhage during delivery, unduly long labor (first stage lasting more than 12 hours), precipitous labor (labor lasting one hour or less), and maternal weight gain of less than 4.5 kg or more than 13.6 kg.

The number of propositi and siblings experiencing each complication, the unadjusted and adjusted relative risk estimates, and the 95% confidence limits around the estimates adjusted for birth order are given in Table 4. As in the case of pregnancy complications, the propositi sustained a higher frequency of labor and delivery difficulties. All eight events were more common for the propositi. The excess ranged from 10% for forceps-aided delivery to 560% for emergency cesarean sections. Emergency cesarean sections were always performed as a result of some prior complication during delivery and were not themselves complications. The reasons for emergency sections were fetal distress (two propositi, one sibling), placenta previa with hemorrhage (one propositus), failed labor (two propositi, one sibling), and cephalopelvic disproportion (five propositi, two siblings). Although the frequency of unfavorable events was low for both propositi and comparison subjects, there is a trend that suggests that autistic children experienced delivery complications more frequently than unaffected siblings. The difference between propositi and siblings was statistically significant only when all complications were grouped together.

Neonatal Complications

History of neonatal complications was obtained primarily from family interviews, as delivery records contained little information on the child's condition beyond birth weight and a comment on the child's general condition and appearance. Except for one instance in which a child was born with only one arm, there was no other medical notation of any malformations, although club feet, hip displacements, and other less severe malformations were reported by the mothers of 22 autistic children and 24 siblings. Information on birth weight and on the newborn's condition, based on strength of cry and color, was obtained from the medical records; data on delayed crying, the presence of malformations, the development of jaundice in the first few days of life, and on need for medical intervention in the first month of life were obtained from the family interview. Table 5 gives the data on neonatal complications.

Jaundice was the only neonatal complication that occurred with approximately equal frequency among propositi and siblings. For all other events, the autistic children bore an increased risk of complications. Medical intervention in the first month of life, including both minor procedures such as intubation and administration of oxygen and major procedures such as surgery, was significantly more common for the autistic children ($P = .05$).

Table 4.—Delivery Complications Recorded in Medical Records

Complication	No. With Complication		Relative Risk*		95% Confidence Interval for Adjusted Relative Risk

COMMENT

Several investigators have evaluated the prenatal and early infancy course of children who had a variety of behavioral disorders, including psychosis and mental retardation. Three of these investigations have concentrated specifically on children with autistic symptomatology.[2,7,14] In these studies, comparison groups have consisted both of siblings and of unrelated children, and of mentally retarded and normal nonautistic children. Results have indicated that in the prenatal phase, autistic children experienced an excess of complications only when compared with normal, unrelated comparison subjects; in the neonatal phase, autistic children had more untoward medical events than any of the three groups of comparison subjects. Specifically, maternal bleeding after the first trimester[15] and low birth weight[1,16] have been identified as variables associated with autism.

The results of the current study support previous findings and suggest that there is a consistent association of unfavorable events in pregnancy, delivery, and in the neonatal phase with autism. It is unlikely that these findings are subject to bias of ascertainment, since most of the analyses used data obtained from medical charts recorded long before autistic symptomatology was noted. While our findings are consistent with those of previous investigators, the interpretation of the results is difficult, as the highest risk ratios were observed for events that involved very small proportions of propositi and siblings, making it unlikely that these complications would account for any substantial number of cases of autism. The frequency of common complications was similar for propositi and unaffected siblings. Furthermore, complications that carried the highest risk of autism represented various kinds of pathologic processes with no apparent unifying feature. This lack of specificity may indicate that various types of physical damage may produce autistic symptomatology, but that no single complication or cluster of complication is responsible for the development of autism.

The data have indicated that an association exists between birth order and autism. If birth order were also related to the complications studied, then birth order could confound the association between pregnancy, delivery, and neonatal difficulties and autism. However, the risk ratios adjusted for the effect of birth order (Tables 3 through 5) do not differ from the unadjusted risk ratios for most of the complications. This finding implies that the first birth order carries an elevated and independent risk of autism that cannot be attributed to the possibly higher frequency of the investigated reproductive complications among first-born children. Nevertheless, one cannot exclude the possibility that other deleterious events or agents, not considered in this study, may be related both to autism and to birth orders. Should such a factor exist, it would be responsible for the observed association of autism and birth order.

The excess of first-born autistic children in small sibships has been noted by previous investigators[17-19] and is unlikely to be the result of bias due to incomplete sibships. In addition, a study by Wing[20] has, like this

investigation, reported both a marked excess of first-born autistic cases among small sibships and a moderate excess of autistic children in the last or penultimate birth orders of large sibships. Interpretation of this finding is complicated because of the bias introduced when one is dealing with incomplete sibships. This bias, which produces greater than expected numbers of cases in last birth orders, is strongest when the condition under study is ascertained at birth and when enrollment of subjects is at the time of diagnosis. The longer the interval between birth and symptom manifestation or between diagnosis and study enrollment, the less the effect of the bias. Although autism is not usually apparent at birth, it is generally diagnosed in early childhood. Thus, the effects of bias may be somewhat muted but cannot be discounted. However, there may be two other explanations for the observed birth order distribution. The first relates to parents' unwillingness to have more children after producing an autistic child. A decision to truncate family size after the birth of an autistic child may be more characteristic of parents who have several children than of parents who have no other children. A second interpretation is suggested by the work of Schoenbaum,[21] who evaluated the role of parity in congenital rubella syndrome. He has reported a bimodal birth order distribution very similar to the one found in our sample. Among cases of documented congenital rubella syndrome, he noted a large excess of first-born, a deficit of second- and third-born, and then again a modest excess of cases occupying birth orders 4 and beyond. The author suggests that the risk of prenatal rubella is greatest for the first-born because their primiparous mothers are not housebound and have work and recreational activities in the community. Children in late birth orders are again at risk because their mothers are potentially exposed to rubella via school-aged siblings. Because of the striking similarity in the birth order distribution among autistic children and victims of congenital rubella, the role of an infectious agent in the development of autism might be considered.

In a previous study,[11] we evaluated a number of infectious agents as possible factors in the etiology of autism. The data showed that, with the exception of prenatal rubella and prenatal influenza, the frequency of all other infectious agents under study was equally low for propositi and siblings. At most, only an estimated 5% of autism could be attributable to prenatal rubella or influenza infection. While these results do not eliminate the possibility of a specific infectious agent in the development of autism, they suggest that should such an agent exist it is not likely to be a common or easily recognized infection.

Fluoride Supplements for Children

A Survey of Physicians' Prescription Practices

Frederick J. Margolis, MD; Brian A. Burt, MPH, PhD; M. Anthony Schork, PhD; Rashid L. Bashshur, PhD; Barbara A. Whittaker, MHSA; Trudy L. Burns, MPH

• **We present the results of a survey to determine how physicians prescribe fluoride supplements for their child patients. A questionnaire was mailed to a representative nationwide sample of 2,604 physicians who treat children. The response rate of completed returns was 49.4%. Results showed that while most respondents prescribed fluoride appropriately, there was some inappropriate prescribing for children receiving fluoridated water. Some physicians also neglected to prescribe for children who were not receiving fluoridated water. Previous differences in recommended schedules of administration between the American Academy of Pediatrics and the American Dental Association may have led to some of these problems. However, these two organizations have now standardized their recommendations.**

(*Am J Dis Child* 134:865-868, 1980)

Although the effectiveness of fluoride in the prevention of dental caries has been well researched, documented, and accepted,[1-6] there is little information regarding the nature and extent of the prescription of fluoride supplements by physicians who care for pediatric patients. Approximately 50% of the nation's children live in areas of the United States with inadequate amounts of fluoride in the water supply.[7] In the absence of school-based preventive programs, these children can receive adequate amounts of fluoride only through prescribed fluoride supplements.

We present the results of a nationwide mail survey among physicians who treat children. The aim of the survey was to determine the physicians' patterns of prescribing fluoride supplements for their child patients. Subsequently, an educational project aimed at improving the identified problems has begun.

This study focused on physicians who treat children, rather than focusing on dentists, because only 13% of American children have visited a dentist by age 5,[8] when all of the primary teeth and most permanent teeth are completely calcified. While it is recommended that all preschool-aged children visit a dentist, until their utilization of dental services improves physicians will carry the primary responsibility for ensuring correct fluoride supplementation among children.

METHODS

Sample Design

The sampling frame, supplied by Ross Laboratories, Columbus, Ohio,[8] was a computerized list of all physicians in the United States identified as having some pediatric practice. Ross Laboratories is continually updating this list, which is their basic source of commercial contact with physicians, and so it was considered to be at least as current as existing physician directories. It had the added advantage of identifying the physicians as pediatricians (both MD and DO) or family practitioners (again, both MD and DO).

The Fluoridation Census of 1975,[7] published by the then Department of Health, Education, and Welfare, was used to identify whether the practice location of physicians was in a fluoridated or nonfluoridated area. A differentiation was made between (*a*) physicians practicing in large fluoridated areas (those with a population over 500,000), (*b*) physicians practicing in less populated fluoridated areas, and (*c*) physicians practicing in nonfluoridated areas. "Fluoridated" was defined as a concentration of 0.7 ppm or more of fluoride in the municipal water supply.

The physician list was stratified by physician type and by fluoridation status of the practitioner's locality. Variable sampling fractions were employed within each stratum to give the desired number of physicians in the sample. Table 1 gives the numbers of physicians selected in the sample and the number of completed questionnaires received.•

Conduct of the Study

The questionnaire was designed to solicit information from the physicians on (*a*) their attitudes toward fluoride supplementation and their perception of their respon-

Physicians Responding				
Pediatricians	103 (51.5%)	350 (56.9%)	510 (65.3%)	**963** (60.3%)
Family practitioners	20 (15.6%)	142 (36.4%)	161 (32.9%)	**323** (32.0%)
Total	**123** (37.5%)	**492** (49.0%)	**671** (52.8%)	**1,286** (49.4%)

Table 2.—Physicians Prescribing Dietary Supplement of Fluoride

Practice	Location of Practice: Large Cities With Fluoridation	Less Populated Fluoridated Areas	Nonfluoridated Areas	Total
Pediatricians	50 (48.5%)	278 (79.4%)	453 (88.8%)	**781** (81.1%)
Family practitioners	7 (35.0%)	70 (49.3%)	126 (78.3%)	**203** (62.8%)
Total	**57** (46.3%)	**348** (70.7%)	**579** (86.3%)	**984** (76.5%)

Table 3.—Recommended Dosage Levels of Supplemental Fluoride

Age, yr	Fluoride Concentration, ppm: 0.0-0.3 (mg/Day)	0.3-0.7 (mg/Day)	0.7+ (mg/Day)
0-2	0.25	0.0	0.0
2-3	0.50	0.25	0.0
3-13	1.00	0.50	0.0

*By age and concentration of fluoride in drinking water, Levels recommended by the American Dental Association and the American Academy of Pediatrics. The American Academy of Pediatrics recommends 16, rather than 13, as the termination age.

sibility in providing the necessary prescriptions, (*b*) their knowledge of the efficacy of fluoride and the need for fluoride supplementation among their patients, and (*c*) their actual practice in prescribing fluoride supplements, including the dosage and ages at which fluoride was prescribed.

The questionnaire, which took about seven minutes to complete, was pretested in a volunteer group of physicians participating in a continuing education program at the University of Michigan Medical School.

The initial mailing of the questionnaires in late 1978 was accompanied by a cover letter individually addressed to each physician. A second mailing after three weeks was made to all physicians who did not return the questionnaire the first time. Finally, a 25% sample of nonrespondents was contacted by telephone in order to request their cooperation in the study. As a result of these efforts, 1,771 of the 2,986 sampled physicians (2,604 MDs and 382 DOs) returned their questionnaires. Three hundred twenty-one of these questionnaires were returned unanswered, 158 by practicing physicians who did not treat pediatric patients. The next most common reason for not answering the questionnaire was that the physician was in specialist pediatric practice. Other reasons for noncompletion were that the sample physicians were interns, administrators, teachers, or researchers. The total number of completed questionnaires returned was therefore 1,450.

Only 164 of the 1,450 completed questionnaires came from osteopaths, and their responses were similar to those given by the medical physician respondents. Because the number of osteopaths in some cells of the analysis was very small, osteopaths were omitted from the results given in this paper. Results given, therefore, are for pediatricians holding MD degrees and family practitioners only. There were 1,286 completed questionnaires received from the 2,604 medical physicians in the sample, a response rate of 49.4%.

RESULTS

Overall recognition of the importance of fluoride in the prevention of dental caries was high; 91.9% of pediatricians and 86.5% of family practitioners responded that usage of fluoride was either important or very important in the prevention of dental caries. More than one third (37.2%) of the physicians correctly identified that ingestion of recommended amounts of fluoride can be expected to reduce the incidence of dental caries in children by 50% to 75%. A further 10.8% of physicians overestimated the potential effectiveness of fluoride, and only 5.7% underestimated the reduction in caries incidence.

More than 94% of the physicians, regardless of the fluoride status of water in their practice location, reported that helping to prevent dental disease by appropriate prescription of fluoride was part of their responsibility to their patients. Yet, when asked whether they prescribed fluoride supplements, 18.9% of the pediatricians and 37.2% of the family practitioners responded that they did not (Table 2). Some of these respondents, of course, were practicing in areas where almost all of their patients were receiving municipally fluoridated water, in which case prescription of supplemental dietary fluorides would be inappropriate. But even among those physicians practicing in nonfluoridated areas, 11.2% of pediatricians and 21.7% of family practitioners reported that they did not prescribe fluoride supplements at all. Table 2 gives the reported prescribing patterns by physician type and location of practice.

At the other end of the scale, 46.3% of physicians in large fluoridated cities and 70.7% of those in smaller fluoridated areas prescribe fluoride supplements. On the face of it, these prescriptions seem inappropriate. However, some patients of these physicians, especially those attending the physicians in smaller fluoridated communities, may have come from adjoining areas without fluoridated water.

Other patients may have been breast-fed infants, who require special consideration (and were the subject of specific questions to be considered later in this report).

While prescribing pediatricians and family practitioners both generally commenced their prescriptions for infants around the recommended[9,10] 3 to 4 months of age, 58.1% of pediatricians and 52.7% of family practitioners prescribed 0.5 mg or more (rather than the now recommended 0.25 mg[9,10]) as the initial daily dose of fluoride supplement. (It should be noted that this survey was conducted before the American Academy of Pediatrics revised its recommended initial dosages down from 0.5 to 0.25 mg/day,[10] so these results are not unexpected.) In addition, 13.8% of pediatricians and 31.9% of family practitioners did not answer this question. Only 59.9% of prescribing pediatricians and 44.8% of family practitioners stated that they revised this initial dosage with increasing patient age. In both groups most physicians said that they did so at about 2 years of age. Among those physicians who revised their dosages, 60.0% of pediatricians and 70.3% of family practitioners both usually discontinued prescribing fluoride supplements at a mean age of approximately 9 years. (Table 3 gives the recommended regimen[9,10] for prescription of fluoride supplements.)

Physicians who do prescribe fluoride supplements were asked for their prescribing practices for infants up to 1 year of age, according to whether the child was breast-fed or bottle-fed and whether the municipal water supply was fluoridated or not. Responses are given in Table 4. Though a substantial majority of these physicians correctly prescribed fluoride where drinking water was not fluoridated, it can be seen that 10% to 13% of pediatricians and 17% to 20% of family practitioners reported that they prescribed fluoride supplement for bottle-fed infants who drink fluoridated water. Such prescriptions are inappropriate, as children receiving an excess of fluoride can later exhibit some mild fluorosis in permanent teeth.[11]

Table 4.—Physicians Prescribing Fluoride for Breast-fed and Bottle-fed Babies

Patient Category; Practice	Patient Age: 0-6 mo Physicians Prescribing No.	0-6 mo Physicians Prescribing %	6 mo–1 yr Physicians Prescribing No.	6 mo–1 yr Physicians Prescribing %
Breast-fed babies; mothers drink fluoridated water				
Pediatrician	343	43.9	421	53.9
Family practitioner	67	33.0	82	40.4
Breast-fed babies; mothers drink nonfluoridated water

Bottle-fed babies, drink nonfluoridated water				
Pediatrician	617	79.0	703	90.0
Family practitioner	167	82.3	170	83.7

COMMENT

The combined response rate of 49.4% (60.3% of the pediatricians and 32.0% of the family practitioners) is reasonable for a mail survey of professionals, but it is still lower than desirable. Results of the survey must be interpreted in light of this response rate. As it is probable that the more conscientious and knowledgeable physicians responded, the deficiencies in prescribing behavior identified may in fact be worse than the results of this survey indicate. With respect to the validity of the sampling frame, the fact that only 158 of 1,771 returned questionnaires (8.9%) were from practicing physicians who did not treat pediatric patients suggested that the sampling frame used was adequate. Both responding physician groups were aware of the benefits of the appropriate supplementation with fluoride and reported acceptance of their responsibility in helping to prevent tooth decay. But unacceptably high proportions of pediatricians and even higher proportions of family practitioners provided no fluoride prescriptions for their patients when a need for them clearly existed (Table 2).

Part of the reason for this gap between knowledge and behavior might be found in the comments given by some of the physician respondents. These comments suggested that some parents were concerned about possible adverse effects of the supplements and that the physicians lacked sufficiently detailed knowledge to answer these concerns. Other physicians reported that some noncompliant behavior had led them to cease prescribing fluoride supplements for all patients. It would thus seem that while physicians are aware of the general effect of fluoride, many require more specific knowledge to help them prescribe it more appropriately.

The need for more information on the use of fluoride supplements was in fact identified by the physicians themselves. Two thirds reported a lack of readily accessible current information concerning the effect of fluoride supplements. They stated that they had learned little about fluoride during their professional education, including the pediatric internship or residencies where applicable, and that they had learned more from continuing education programs, professional journals, and dentists.

A major area of concern identified in the study was that most respondents who did prescribe fluoride supplements prescribed too high a dosage

at an early age and then ceased prescribing too early. Supplementation for fluoride should continue until eruption of all teeth (except the third molars) has been completed, that is, usually until age 13.[9]

Probably the major reason for the prescription of higher-than-necessary doses at an early age was the previous differences between the dosage schedules recommended by the American Academy of Pediatrics (AAP) and the Council on Dental Therapeutics of the American Dental Association (ADA). The AAP has recently revised its recommendations to bring them into line with those of the ADA[10]; what is now the jointly recommended schedule is given in Table 3. The one minor difference in the schedules recommended by the two bodies is in termination age.

Varying degrees of mild enamel fluorosis have been reported[12,13] at the higher dosages previously recommended by the AAP,[14] although others have not found such to be the case.[2] The ADA acknowledges the need for additional research on the most suitable dosage schedule for fluoride supplementation,[15] although the current empirically derived schedule is conservative and has evolved cautiously with the experience of many years. However, it can be stated that there is little justification for a child drinking fluoridated water to receive supplemental fluoride.

Breast-fed infants in a non-fluoridated area should receive fluoride supplementation from birth,[15,16] as this regimen will give additional protection to the calcifying primary teeth with little risk of fluorosis in the permanent dentition. A modified approach is required where water is optimally fluoridated. Although human milk contains insignificant amounts of fluoride,[17] the attending physician needs to determine whether the child is being totally breast-fed or whether the diet is being supplemented by additional food and water. If the latter, physicians in fluoridated areas are advised not to prescribe fluoride supplements in order to avoid the risk of mild enamel fluorosis. If the physician is confident that the child is being totally breast-fed, the AAP-ADA schedule in Table 3 can be followed until weaning,[16] regardless of fluoridation status.

The educational follow-up to this study, designed to provide comprehensive information on fluoride to all practicing physicians who treat children in the United States, seeks to provide all of these physicians with audiotapes, films, and exhibits on recommended fluoride supplementation. All teaching institutions will also receive a portfolio on the subject. It is hoped that this project will serve to remedy the deficiencies in prescribing fluoride identified in this project.

Both the survey and the educational program are supported by a grant from the W. K. Kellogg Foundation, Battle Creek, Mich.

CNS Manifestations of the Hemolytic-Uremic Syndrome

Relationship to Metabolic Alterations and Prognosis

James F. Bale, Jr, MD; Craig Brasher, MD; Richard L. Siegler, MD

• To define the CNS manifestations of the hemolytic-uremic syndrome (HUS), the records of 61 consecutive episodes of HUS in 60 patients were reviewed. Major CNS signs (seizures and/or coma) occurred in 30 of the 61 episodes. Twenty-four children had seizures. Analysis of blood pressure and metabolic parameters on admission to the hospital did not predict which child would exhibit CNS signs. However, during the subsequent course of the illness, children with CNS dysfunction had lower minimum serum sodium concentrations and more severe azotemia and were more likely to require dialysis than children without CNS signs. Of the 61 episodes, there were three deaths, and three children suffered major CNS sequelae. Coma at the time of admission and elevated CSF protein levels were features associated with poor outcome.

(*Am J Dis Child* 134:869-872, 1980)

The hemolytic-uremic syndrome (HUS) is the most common cause of acute renal failure in infants and young children. The principal features include (1) antecedent gastroenteritis or upper respiratory tract infection, (2) acute onset of microangiopathic hemolytic anemia and thrombocytopenia, (3) acute renal failure, and (4) frequent involvement of the CNS.[1-5]

To define factors important in the pathogenesis of the CNS abnormalities and to identify features that predicted death or CNS sequelae, a detailed retrospective study of the clinical and laboratory features of 61 episodes of HUS in 60 children were performed.

PATIENTS AND METHODS

Patient Population

The records of 61 consecutive episodes of HUS in 60 patients (one child had two distinct episodes) admitted to the Primary Children's and University of Utah Medical Centers, Salt Lake City, between the years of 1972 and 1978 were reviewed. The cases represented a referral population from the states of Utah, Wyoming, and Idaho. The children ranged in age from 3 months to 13 years (average age, 3.3 years). No epidemics of HUS were identified during the seven-year study interval.

Clinical Features

The features of the prodromal illness included diarrhea and vomiting in over 90% of the children. Fever, pallor, symptoms of upper respiratory tract infection, and oliguria occurred less commonly. The subsequent clinical course included oliguria or anuria in 64% and hypertension in 51% of the cases. Thirty-three children (54%) required dialysis (BUN level, >150 mg/dL) and 39 (65%) of the children received one or more blood transfusions.

Central nervous system dysfunction was seen in 30 of the 61 episodes (48%) (Table 1). Twenty-four children experienced seizures, and alterations of consciousness without seizures occurred in an additional six children. The seizures were generalized tonoclonic in 20 children and focal in four. In most children the seizures occurred early in the illness (average, 6.5 days after the onset of the prodrome) and were often seen within the first 72 hours after admission. In nine children, a seizure was the clinical manifestation that led to the child's hospi-

Table 1.—Acute Neurologic Complications in Hemolytic-Uremic Syndrome (61 Episodes)

Complications	No.	%
Seizures	24	40
Generalized	20	33
Focal	4	7
Altered consciousness without seizures	6	10
Decerebrate posturing	2	3
Hemiparesis (transient)	1	2

talization. When seizures did occur, they were usually isolated events, and in only nine children did multiple seizures (more than two) occur.

Although alterations of consciousness were common and included a spectrum from lethargy to coma, profound coma at the time of admission was unusual and occurred in only five of the 61 episodes. Two children demonstrated decerebrate posturing and one child experienced a transient hemiparesis in association with focal seizures.

Laboratory Features

Values from the following laboratory studies were obtained for all children on admission to the hospital: serum sodium, glucose, calcium, hematocrit, BUN, and creatinine. Admission laboratory values were defined as the initial laboratory assessment obtained either at the referral hospital or at the Primary Children's and University of Utah Medical Centers for those admitted directly. Mean values and ranges for these laboratory parameters are presented in Table 2. For each child the lowest serum sodium, lowest calcium, lowest hematocrit, highest BUN, and highest creatinine value that occurred during hospitalization were also compiled (Table 3). All children exhibited proteinuria and hematuria, and in 72% a BUN level greater than 100 mg/dL was observed. The hematocrit was less than 25% and the platelet count was less than 100,000/cu mm in 97% and 74% of the children, respectively.

In children who incurred CNS symptoms during the course of their HUS illness, values for serum sodium, glucose, calcium, hematocrit, BUN, creatinine, blood pressure, and temperature were obtained at the time of the child's acute CNS dysfunction (Table 4).

Nineteen of the 30 children with CNS symptoms underwent lumbar puncture. The CSF glucose concentrations were normal and pleocytosis was absent, but two of the 19 children had an elevated CSF protein concentration (>50 mg/dL). An EEG was obtained in 11 of the 30 children who exhibited CNS symptoms. The EEG was diffusely slow in nine, normal in one, and isoelectric in one child who died within 48 hours after the onset of his illness. Three children exhibited epileptiform spike and/or sharp wave discharges.

Table 2.—Admission Laboratory Values*

Laboratory Values	CNS Signs and Symptoms: Present (N = 30) Mean ± SD	CNS Signs and Symptoms: Absent (N = 31) Mean ± SD	P†
Serum sodium, mEq/L	130 ± 8 (113-145)	135 ± 9 (107-146)	< .05
Blood glucose, mg/dL	133 ± 74 (49-386)	108 ± 28 (60-127)	NS
Serum calcium, mg/dL	8.0 ± 1 (6.0-10.3)	8.3 ± .9 (7-9.3)	NS
Hematocrit, %	30.5 ± 8 (19-45)	26.4 ± 9 (16-48)	NS
BUN, mg/dL	99.7 ± 63 (12-246)	75.8 ± 53 (9-203)	NS
Serum creatinine, mg/dL	6.6 ± 4.9 (0.5-17.0)	3.3 ± 3.1 (0.5-12.7)	< .01

Table 3.—Extremes of Laboratory Values*

Laboratory Values	CNS Signs and Symptoms: Present (N = 30) Mean ± SD	CNS Signs and Symptoms: Absent (N = 31) Mean ± SD	P†
Lowest serum sodium, mEq/L	124 ± 6 (113-140)	132 ± 8 (106-142)	< .001
Lowest serum calcium, mg/dL	7.5 ± 1 (5.3-8.9)	8.1 ± .8 (7-9.3)	NS
Lowest hematocrit, %	17.5 ± 3.5 (13-30)	18.6 ± 4.4 (12-35)	NS
Maximum BUN, mg/dL	158 ± 52 (27-295)	104 ± 65 (14-257)	< .01
Maximum serum creatinine, mg/dL	8.9 ± 4.8 (0.9-19.8)	4.9 ± 4.5 (0.5-15.6)	< .01

*Numbers in parentheses indicate range.
†Student's *t* test.

Comparison of laboratory parameters between subpopulations of children who did and did not exhibit CNS symptoms gave the following results. Admission laboratory studies (Table 2) revealed no significant differences ($P > .05$, Student's t test) in serum glucose, calcium, BUN, or hematocrit values. Slight differences in sodium ($P < .05$, Student's t test) and creatinine ($P < .01$, Student's t test) concentrations were seen, however. In the subsequent hospital course (Table 3), the children with CNS dysfunction tended to have lower minimum serum sodium ($P < .001$, Student's t test), higher BUN ($P < .01$, Student's t test), and higher serum creatinine ($P < .01$, Student's t test) concentrations than children who were without CNS complications. The higher BUN and serum creatinine values in the children with CNS complications resulted in more frequent peritoneal dialysis. The criterion for dialysis was a BUN concentration greater than 150 mg/dL. Twenty-four of the 30 children with CNS symptoms required dialysis. In contrast, only nine of 31 children who were free of CNS disease required dialysis. Peak BUN levels among children who underwent dialysis did not differ for either group (mean, 175 mg/dL).

MORBIDITY AND MORTALITY

Of the 60 children in this series, 57 (95%) are alive at one to seven years following their illness. Two deaths (3%) occurred during the acute phase of HUS, and one child died subsequently from a complication of chronic renal failure. Long-term major renal sequelae among survivors include hypertension in three (5%) and chronic renal failure in one child. Three children (5%) have suffered major neurologic sequelae. One child has generalized seizures, one exhibits psychomotor retardation, and one child is

retarded and cortically blind. Major renal and neurologic sequelae have occurred concurrently in only one child. All of the children who died of acute HUS or sustained permanent damage to the nervous system were among the children who experienced CNS dysfunction during the acute phase of HUS.

COMMENT

Several authors, in particular Gianantonio and associates, have emphasized the importance of neurologic signs and symptoms in HUS.[2,5,8] Neurologic abnormalities can be minor, such as irritability, lethargy, and ataxia, but are often severe and include seizures, coma, and hemiparesis. In the series of 678 patients described by Gianantonio et al, 41% experienced major CNS dysfunction (stupor, coma, convulsions, and/or hemiparesis).[5] Other authors have encountered serious neurologic complications less frequently.[1,6]

In this study, 30 of the 60 children (50%) exhibited major CNS dysfunction during their illness. Seizures occurred in 24 (40%), and stupor or coma without seizure activity was seen in an additional six children (10%). Decerebrate posturing and transient hemiparesis were considerably less frequent. When seizures did occur, they were usually brief and were rarely recurrent. They often occurred early in the illness, and in nine children (15%) a seizure was the clinical feature that led to the child's hospitalization. In the majority of childen acute anticonvulsant therapy with phenytoin sodium, phenobarbital, and/or diazepam was utilized, but in only two children was anticonvulsant therapy continued at the time of discharge from the hospital.

Several mechanisms have been proposed to explain the CNS symptoms that accompany HUS. It has been suspected that the neurologic features could be the result of vascular occlusive lesions similar to those which are present in the kidney. However, such CNS lesions have only rarely been identified. In one of the few detailed neuropathological investigations of children who died during the acute stages of HUS, Rooney and co-workers[8] were unable to identify a distinctive neuropathologic process which could be considered typical for HUS.[10] The changes they noted were nonspecific and consisted primarily of edema and hypoxic damage. In contrast, Upadhyaya and co-workers suggested that microthrombi may be found in numerous organs, including the brain. They identified cerebral microthrombi in two of three autopsied cases.[11]

In our series, one of the two deaths from acute HUS (case 22) came to

autopsy. Although microthrombi were identified in the kidneys, microthrombi were not seen in the CNS. Edema and anoxic damage were the only neuropathologic abnormalities noted.

The numerous metabolic alterations that occur during HUS have also been implicated in the pathogenesis of the CNS dysfunction. Gianantonio and others have indicated that in some cases hypotonic overhydration, hypoglycemia, hypocalcemia, hyponatremia, or changes in serum osmolality have been associated with the CNS symptoms.[1,5,7] Hypertension has been cited as an additional factor.[9]

In this series, analysis of blood pressure and admission laboratory parameters (Table 2) did not predict which child would exhibit CNS dysfunction during the subsequent course of HUS. However, among the 30 children in whom CNS symptoms did develop, potential immediate metabolic causes could be identified in more than half (Table 4). Hyponatremia (Na^+ <130 mEq/L) and/or vigorous hydration with hypotonic fluids was temporally associated with seizures or altered consciousness in 17 children and an additional ten children had hypocalcemia (Ca^{++} <8.0 mg/dL). One child (case 6) was febrile (temperature >38.6 °C). Two additional children (cases 7 and 30) experienced late onset seizures (days 14 and 15 of illness) following peritoneal dialysis. No child had hypoglycemia (glucose <45 mg/dL) or hypertensive encephalopathy at the time of acute CNS dysfunction.

Our patients with CNS symptoms had lower minimum serum sodium concentrations, higher peak BUN and serum creatinine concentrations, and were more likely to require dialysis during the subsequent course of HUS than were children without CNS signs or symptoms (Table 3). This suggests that a combination of metabolic alterations may have been operative in the pathogenesis of the CNS dysfunction in our patients. This is further supported by the observation that children with seizures and/or coma were more likely to have a low serum sodium concentration (<130 mEq/L) and/or a high BUN level (>100 mg/dL) during their illness than were children without CNS signs ($P < .001$; χ^2).

Long-term morbidity occurred in six of the 60 children in this series (10%). Three suffered major damage to the nervous system. As suggested by both Rooney and associates[8] and Gianantonio and associates,[5] the occurrence of CNS dysfunction was associated with increased morbidity and mortality. All of the children who died of acute HUS (2/60) or incurred major CNS sequelae (three of 57 survivors) were among children who experienced CNS dysfunction during the acute phase of HUS. Coma at the time of admission was the most important predictor of outcome, and of the five children who were comatose on admission, two died and two were left with severe CNS sequelae. Although seizures were common during the acute stage of HUS, they did not by themselves predict death or CNS sequelae.

The level of CSF protein was an additional feature that may assist in predicting prognosis. Of the two children with elevated CSF protein levels (>50 mg/dL), one died of acute HUS and the other was rendered cortically blind. None of the other 17 children with normal CSF protein levels experienced death or poor outcome ($P < .001$; χ^2).

Patricia Gay, PhD, provided statistical assistance. Margaret Grunnet, MD, assisted with the neuropathologic examinations.

Inappropriate Secretion of Antidiuretic Hormone After Open Heart Surgery

Stanislaus Ting, MD, Eshagh Eshaghpour, MD, FRCP(C)

• **After open heart surgery for the closure of an atrial septal defect, acute brain syndrome developed in a 5-year-old girl, this being documented by laboratory evidence of the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Irritability and total disorientation were the first symptoms observed. She completely recovered after being treated with hypertonic saline solution and fluid restriction. The potentially serious outcome of the SIADH warrants early recognition and appropriate measures in children who suffer acute brain syndrome after open heart surgery.**

(*Am J Dis Child* 134:873-874, 1980)

Since the original description by Schwartz et al in 1957,[1] the syndrome of inappropriate antidiuretic hormone secretion (SIADH) has been recognized in postoperative patients and in association with many disorders, including CNS disease, malignant neoplasms, and pulmonary diseases.[2] However, the SIADH has not, to our knowledge, been reported in children after open heart surgery. In this communication, we describe a child in whom symptomatic hyponatremia was manifested clinically as acute brain syndrome[3] that occurred after surgical closure of an atrial septal defect.

REPORT OF A CASE

A 5-year-old girl was hospitalized for surgical closure of an atrial septal defect. Cardiac catheterization had revealed a secundum atrial septal defect with a pulmonary-to-systemic blood flow ratio of 2 and normal pulmonary artery pressure. On admission, the child appeared to be healthy, alert, and well oriented. Her temperature was 37 °C; blood pressure (BP), 100/70 mm Hg; heart rate, 85 beats per minute; and respirations, 26/min. Her weight was 21 kg and her height 110 cm. Neurologic examination revealed no abnormalities. A grade 3/4 blowing ejection systolic murmur was present at the left upper sternal border. The splitting of the second heart sound was wide and fixed. The ECG and chest roentgenogram were compatible with an atrial septal defect. Her hemoglobin concentration was 12.5 g/dL; serum sodium level, 140 mEq/L; serum potassium level, 4.1 mEq/L; serum chloride level, 100 mEq/L; serum bicarbonate level, 22 mmole/L; BUN level, 12 mg/dL; serum creatinine level, 0.6 mg/dL; serum calcium level, 9 mg/dL; and fasting blood glucose level, 60 mg/dL. Urinalysis results showed normal findings and a specific gravity of 1.020.

Surgery was performed using cardiopulmonary bypass at 32 °C. The extracorporeal circuit was primed with 1,500 mL of whole blood and 200 mL of lactated Ringer's solution. The total bypass time was 30 minutes. An atrial septal defect of the foramen ovalis type, 1.5 × 2 cm, was closed uneventfully. However, there was a 300-mL blood loss after closure of the atriotomy. This blood was adequately replaced, and the bleeding stopped after administration of 100 mL of fresh frozen plasma. The first postoperative day was uneventful. Her temperature was 37.2 °C; BP, 100/60 mm Hg; heart rate, 100 beats per minute; and respirations, 30/min. Serum electrolytes, BUN, and urinary specific gravity values were normal (Table).

On the second postoperative day, the patient suddenly became extremely irritable, uncooperative, and completely disoriented. Her temperature was 37.4 °C; heart rate, 110 beats per minute; respirations, 33/min; and BP, 110/70 mm Hg. The patient had not received barbiturates or morphine in the past 24 hours. Neurologic examination revealed no focal deficits. However, the deep tendon reflexes were diminished. There were no signs of dehydration or peripheral edema. The laboratory studies revealed the following values: serum sodium, 121 mEq/L; serum osmolality, 252 mOsm/kg; simultaneous urine osmolality, 850 mOsm/kg; and urine sodium, 170 mEq/L. The serum potassium level was 4.5 mEq/L; serum chloride level, 93 mEq/L; serum bicarbonate level, 20 mmole/L; BUN, 4 mg/dL; serum calcium level, 9 mg/dL; serum magnesium level, 1.5 mg/dL; and urinary specific gravity, 1.038. The blood glucose level was 180 mg/dL during the acute stage but the subsequent determinations were in the normal range. The SIADH was suspected, and the sodium requirements to correct the serum sodium level from 121 to 130 mEq/L were calculated (Δ serum sodium concentration × body weight [kg] × 0.6). A total of 113 mEq of sodium was administered as 3% sodium chloride solution. The patient's irritability disappeared within a period of ten minutes after 30 mL hypertonic saline solution was given. The remaining 100 mEq of sodium chloride was infused over the ensuing four hours. The fluid intake was restricted to 700 mL/sq m/24 hr plus replacement of nasogastric and chest tube drainage. The serum sodium level was restored to the normal 134 mEq/L, serum

Laboratory Data and Fluid Therapy*

	Postoperative Day

Left, Alterations in serum and urine sodium levels. Right, Osmolality after occurrence of symptoms. Laboratory measurements were obtained at four-hour intervals.

osmolality increased to 290 mOsm/kg, and urinary sodium excretion decreased to 30 mEq/L within a period of four hours. Her serum sodium level was maintained at 138 to 142 mEq/L by fluid restriction during the next five days. Fluid therapy and laboratory values are summarized in the Figure and Table.

COMMENT

The patient described in this case report had the hallmarks of the SIADH, including hyponatremia, serum hypoosmolality, and urine hyperosmolality with natriuresis. Her cerebral dysfunction was terminated on infusion of hypertonic saline solution. In addition, her serum sodium level increased and her clinical condition improved with fluid restriction. The presence of normal renal function, normal potassium levels, absence of dehydration or edema, and continuous favorable response to fluid restriction, further support the diagnosis of the SIADH in this 5-year-old child.

The antidiuretic hormone (ADH) is synthesized in the supraoptic nuclei of the hypothalamus and is carried to the posterior pituitary gland via the neurohypophysial tracts. The principal factors regulating release of ADH include the osmotic pressure of plasma and the circulating blood volume. The main action of ADH is to decrease renal excretion of free water. This mechanism normally maintains plasma osmolality within a narrow range. The change in plasma osmolality from full diuresis to the initiation of antidiuresis is approximately 2%.[4] It is generally believed that retention of water with low serum sodium levels, occurring postoperatively, results from inappropriate secretion of ADH. However, the mechanisms causing release of ADH postoperatively are not clearly understood.

The abrupt changes in hemodynamic equilibrium that occur with hemorrhage or total cardiopulmonary bypass have been associated with the SIADH.[5] Hypoperfusion resulting from hemorrhage could lead to prolongation of the half-life of ADH.[4] Blood loss can also trigger the volume and pressoreceptors, resulting in increased release of ADH.[4] In addition, hemorrhage could decrease the mean renal arterial pressure and increase renin secretion, leading to production of angiotensin II, which acts on the CNS and stimulates ADH production.[6] Factors often associated with surgery, such as stress, tissue trauma, visceral manipulation, narcotics, and anesthetic agents, stimulate the release of ADH.[7,8]

Inappropriate secretion of ADH, resulting from one or possibly a combination of the above multiple mechanisms, caused hyponatremia and initiated an acute brain syndrome[3] in this child. The clinical picture in this patient was highlighted by abrupt personality changes, extreme irritability, and transient loss of hearing and visual perception. This type of manifestation is often related to cerebrovascular accidents after cardiac surgery. An awareness of the SIADH is required to make a prompt diagnosis and to institute treatment. The potentially serious outcome of the SIADH warrants early recognition and appropriate measures. The possibility of the SIADH must be considered in children showing symptoms of cerebral dysfunction after open heart surgery.

Review

Acute Iron Poisoning

A Review

James L. Robotham, MD, Paul S. Lietman, MD, PhD

The accidental ingestion of iron-containing preparations is relatively common in childhood, and intentional overdosage with iron is occasionally seen in adults. Though rarely fatal, the consequences of a substantial iron ingestion can result in profound mental retardation or death. The availability of deferoxamine mesylate, a specific and tenacious chelator of iron, and the necessity for its early administration demand that the physician be aware of a rational approach to the therapy for iron poisoning.

Owing to our current understanding of the pathophysiology of iron poisoning, we believe that the simultaneous oral and continuous intravenous (IV) administration of deferoxamine offers the most rational specific therapy for this condition. In this review we shall outline the clinical description, pathophysiology, and therapeutic regimens for acute iron intoxication. We have used this information to derive an approach we believe to be reasonable.

CLINICAL DESCRIPTION

The oral lethal dose (LD) of elemental iron is generally accepted to be 200 to 250 mg/kg, with the most common form of ferrous sulfate tablets being 20% elemental iron by weight.[1] However, this must not be used as an absolute value, since Arena states that as few as ten ferrous sulfate tablets (130 mg of elemental iron) have been fatal to a small child.[1]

The clinical description of acute iron poisoning has been well presented in several previous reviews.[2-8] Covey has emphasized four stages of iron poisoning.[9] The first stage occurs within six hours and is potentially, though rarely, fatal. It may include vomiting, an explosive diarrhea, irritability, abdominal pain, seizures, lethargy, and coma. Direct irritation of the gastrointestinal (GI) mucosa by iron tablets may lead to life-threatening acute hemorrhagic gastritis. Tachypnea, tachycardia, hypotension, and metabolic acidosis may occur. Other nonspecific laboratory findings during this stage may include a leukocytosis and hyperglycemia. During this first stage, the plasma iron level will be high after a significant ingestion.[5,10] However, due to the rapid clearance of iron from the plasma and its deposition in the liver, plasma iron levels may be deceptively low within a few hours of a substantial ingestion.[11,12] Consequently, at the time of initial clinical observation a severely toxic condition may be associated with only minimally elevated plasma iron levels.[3,4,12] The severity of the poisoning may be difficult to assess at this early stage. Westlin has emphasized the importance of shock or coma during this period as a grave prognostic index.[2,5]

After the first stage, there may be a period of deceptive quiescence. This period may extend up to 48 hours but is usually of less than 24 hours' duration.

A third stage may begin 12 to 48 hours after a substantial ingestion and may include shock, hypoperfusion, and hypoglycemia.[12,13] Again, it is important to note that serum iron levels may be normal during this stage.[2,3,5,14] Elevated levels of SGPT may reflect liver damage.[13,15] This stage appears to occur infrequently but its presence is ominous.

Late-appearing sequelae, constituting a fourth stage, may include pyloric or antral stenosis, hepatic cirrhosis, and CNS damage.[9,16]

PATHOPHYSIOLOGY

The pathophysiology of iron intoxication is complex and incompletely understood. Iron is absorbed by a first-order process even after massive doses.[7,12,17-20] The absorbed iron, possibly in the form of ferritin, causes a massive postarteriolar dilation with subsequent venous pooling. Total peripheral resistance increases to maintain a normal blood pressure (BP). A marked increase in capillary permeability leads to plasma loss and a rise in hematocrit level and in blood viscosity while blood volume, central venous pressure, and tissue perfusion decrease. Subsequently, the decreasing cardiac output leads to a state of shock and to cardiac failure, this state being reflected by an increased central venous pressure and tissue hypoperfusion that are associated with progressive cellular hypoxia and acidosis. The acidosis associated with iron poisoning may also be partially explained by the release of protons that are associated with the oxidation of the ferrous iron and subsequent hydration of the ferric iron.[7]

Once plasma transferrin has been saturated, absorbed iron is distributed into cells. The liver appears to be the primary site of uptake.[11] Although iron is initially taken up by Kupffer cells, it rapidly moves to hepatic parenchymal cells.[21-23] Electron microscopic studies localize the subcellular distribution of iron to the area of the mitochondrial cristae, the site of the electron transport system.[22,23] This occurs prior to morphologic or biochemical evidence of cellular damage. The mitochondrial localization appears to be critical to our understanding of many of the toxic effects of iron. Iron causes mitochondrial swelling, a rather nonspecific index of mitochondrial dysfunction.[23-27] One explanation for the mitochondrial dysfunction that is produced by iron is provided by the known action of ferrous ions as potent catalysts of lipid peroxidation. Experimental evidence for this action includes the thiobarbiturate acid reaction, the production of malonaldehyde, and the increased consumption of oxygen.[24,25,28-33] Lipid peroxidation induced by ferrous ions has been associated with marked alterations in mitochondrial membrane composition and in functions of both the Krebs cycle and the electron transport system.[29] Mitochondria may be particularly susceptible to lipid peroxidation as a result of the high concentration of polyunsaturated fatty acids in their membranes.[34] Double carbon bonds in the polyunsaturated lipids can be disrupted by reacting with the free-radical singlet oxygen. Lipid peroxidation catalyzed by ferrous iron may thus change membrane permeability so as to allow rapid intramitochondrial accumulation of additional iron and may directly alter the steric configuration of the mitochondrial membrane, which is essential for the proper functioning of the electron

transport system and thus for aerobic respiration. The potential for biologic toxicity of lipid peroxidation has been increasingly recognized. The pulmonary sequelae of oxygen toxicity may be mediated through lipid peroxidation.[35] The roles of iron and vitamin E supplements as causes and treatments, respectively, of the anemia of prematurity have been investigated.[36,37] There appears to be an age-dependent development of biologic protective mechanisms (superoxide dismutase) in many tissues, including the lung and the liver.[35,38] Thus, if lipid peroxidation is an important contributing mechanism in iron's toxicity, the younger patient may be at greater risk. Also, it would be predicted that iron's toxicity would be manifested depending on the relative concentrations of iron and polyunsaturated lipids and that it would result in multiorgan dysfunction.

Another plausible explanation for the mitochondrial damage produced by iron is based on the ability of iron to act as an electron sink, resulting in the shunting of electrons away from the electron transport system.[39] The reduction of ferric iron, the predominant ionic form of iron at a pH of 7, by an enzyme located on the inner mitochondrial membrane normally functions to provide ferrous iron for insertion into protoporphyrin IX. In the presence of an iron overload, this same enzyme might reduce the massive amount of excess ferric iron to ferrous iron, which in turn would be promptly oxidized back to the ferric state in the presence of intramitochondrial oxygen. Thermodynamic considerations of this system would favor the shunting of electrons away from the electron transport system, thereby diminishing oxidative phosphorylation and reducing the adenosine triphosphate (ATP) that is generated.[39] If this mechanism were operative, experimental observations would demonstrate oxygen uptake without ATP formation. The same finding could also be interpreted as an uncoupling of mitochondrial oxidative phosphorylation in which oxygen would also be used without ATP being formed.[24,30] A number of observations of iron metabolism in normal and in iron-intoxicated states are consistent with the hypothesis that iron acts as an electron sink.[23,40] The end result of this process would be cellular dysfunction and ultimately death due to the impaired generation of ATP. The fact that absorbed iron can neither be detoxified nor rapidly excreted markedly enhances susceptibility to acute iron poisoning.[41]

THERAPY

As a common denominator in the therapy of most iron poisonings, consideration should be given to the prevention of continued absorption, the enhancement of elimination, and the prevention or reversal of the cellular pathophysiology. With respect to iron poisoning, the chelating agent, deferoxamine, would appear to beneficially influence each of these processes. Deferoxamine is a highly specific chelator of ferric (Fe^{3+}) iron with an affinity for iron (10^{31}) that is more than ten times greater than any other known chelator of iron. Deferoxamine has an affinity constant for iron two orders of magnitude greater than does transferrin.[42-44] One hundred milligrams of deferoxamine is capable of binding 9.35 mg of elemental iron.[45]

Deferoxamine—Mechanism of Action

The protective effect of deferoxamine given orally appears to be due to its ability to bind iron in the gut and thus prevent absorption of the ingested iron. The usual explanation given for the effectiveness of parenteral deferoxamine involves the enhancement of iron elimination through the formation of the water-soluble, renally excreted ferrioxamine. Though this may be of major importance in the effectiveness of parenteral deferoxamine, several reports suggest that the urinary elimination of iron may be insufficient to account for the drug's effectiveness.[6,46,47] Thus it may be that deferoxamine also exerts a protective effect at the cellular level.[48] The chelation of iron by deferoxamine in the extracellular space may limit the entry of iron into cells by virtue of the decreased membrane permeability of ferrioxamine, thus preventing an intracellular toxic state. Second, deferoxamine could enter cells and chelate extramitochondrial iron.[45] The ferrioxamine that is formed might well remain outside of the mitochondria, thus preventing the movement of iron to the potentially critical area of the inner mitochondrial membrane.[40] Third, if deferoxamine does enter mitochondria, then intramitochondrial deferoxamine could bind intramitochondrial iron and might limit mitochondrial injury that results from lipid peroxidation.[33] This last explanation would not be applicable if the mechanism of iron toxicity involves the shunt mechanism mentioned above, since ferrioxamine has been shown to be capable of providing iron as a usable substrate for the reducing enzyme of the inner mitochondrial membrane.[40]

Deferoxamine—Pharmacokinetics

The rational use of deferoxamine requires an understanding of its pharmacology. Deferoxamine complexes preferentially, if not exclusively, with the ferric ion.[43] Most commonly, medicinal iron is in the ferrous ion because it is better absorbed.[17] The rate and extent of the chelation of iron by deferoxamine can be markedly increased by changing the pH of the medium from 2 to 6. This increase has been attributed to the rapid oxidation of the ferrous to the ferric ion accompanying the increase in pH.[43] The product of the chelation of ferric iron with deferoxamine, ferrioxamine, is quite stable at physiologic pH.

Deferoxamine is poorly absorbed when administered orally and thus might be expected to remain in the GI tract and bind unabsorbed iron.[44,45] Conclusive studies on the fate of the bound iron, ferrioxamine, in the GI tract are not, to our knowledge, available. However, Keberle has stated that ferrioxamine is poorly absorbed from the gut,[44] and Misra et al have confirmed this in vitro.[49] After the oral administration of crystalline ferrioxamine to dogs, Whitten et al reported the renal excretion of 3.4% to 22.2% of the dose, this suggesting some absorption of the ferrioxamine.[19] The clinically relevant questions, however, are whether or not oral deferoxamine will decrease the absorption of orally administered iron and whether the toxicity of the chelate thus formed is substantially less than that of the free iron. Evidence for a decrease in absorption of iron with oral deferoxamine has been provided by Keberle,[44] by Balcerzak et al,[50] by Bannerman and Malpas,[51] and by Hwang and Brown.[52] In addition, several studies have demonstrated the marked reduction in mortality in experimental iron poisoning when associated with the oral use of deferoxamine.[45,53]

Once absorbed, deferoxamine is distributed into a volume equal to 60% of the body weight. Ferrioxamine, on the other hand, is distributed into a volume corresponding to only 20% of the body weight.[44,54,55] This would suggest that ferrioxamine remains in an extracellular compartment, whereas deferoxamine may enter cells. In vitro experiments have demonstrated that ferrioxamine is excluded from the mitochondria.[40]

Deferoxamine is rapidly metabolized to inactive products by plasma as well as by other tissues.[42,44,54,56] After IV administration to nephrectomized dogs, the serum half-life of deferoxamine is about one hour.[42,54] This rapid elimination of deferoxamine may be important in the construction of an adequate dosage regimen. Ferrioxamine, on the other hand, is very slowly metabolized and is eliminated primarily unchanged in urine, with a clearance approximating the glomerular filtration rate.[54,56] In normal dogs, 94% of an intrave-

nously administered dose is recovered in the urine within five hours, while in nephrectomized dogs the serum half-life is markedly prolonged, suggesting a lack of other routes of elimination.[54] Ferrioxamine is a dialyzable, water-soluble complex.[19]

Deferoxamine—Toxicity

The toxicity of deferoxamine, if properly used, is minimal. It includes GI discomfort after oral administration and hypotension with excessively rapid IV administration of large doses. The toxicity of ferrioxamine has not, to our knowledge, been systematically studied, but some experimental data suggest that the toxicity of ferrioxamine is less than that of iron itself.[19]

Deferoxamine—Efficacy

Ultimately, the clinical usefulness of deferoxamine in acute iron intoxication rests on the demonstration of its therapeutic effectiveness. Since it is exceedingly difficult to acquire this evidence in human iron intoxication, we must rely heavily on studies in experimental animals.

Published evidence for the effectiveness of parenterally administered deferoxamine is meager. Tripod[53] has shown the mortality to be decreased from 75% to 20% to 30% if subcutaneous deferoxamine is given between 30 and 120 minutes after oral iron. Hosking has demonstrated that the dose of iron necessary to kill 50% of his mice was increased fivefold when the animals were treated with intramuscular (IM) deferoxamine.[57] On the other hand, Whitten has reported that the use of IV deferoxamine failed to provide protection for orally poisoned dogs.[3]

A sizeable amount of data would appear to support the efficacy of orally administered deferoxamine. Several human studies, using non-LDs of iron, have demonstrated the ability of oral deferoxamine to diminish the absorption of oral iron.[50,52] Similar results have been reported in experimental animals.[44,51] Oral administration of deferoxamine protected 75% of mice from an oral iron dose that should have been lethal to 75%.[53] Moeschlin and Schnider have demonstrated a 60% survival rate in guinea pigs that were given a dose of iron calculated to kill 100% of the animals.[45] Both of these reports emphasized the importance of providing the deferoxamine soon after the iron has been ingested since efficacy decreased with time after ingestion.

A lack of effectiveness of oral deferoxamine has been suggested by Whitten, who has shown a lack of protection in four dogs given LDs of iron.[3] After a similar dose of iron was given orally to five dogs as the crystalline ferrioxamine complex, all were alive after 24 hours and only two had died after 48 hours. Fourteen control dogs given the same dose of free iron had died within ten hours. These latter experiments appear to be the basis for the belief that oral deferoxamine is contraindicated in iron poisoning. On the contrary, we believe that these results should be interpreted as evidence in favor of the therapeutic effectiveness of oral deferoxamine. Thus, a 60% survival rate was realized when an otherwise LD of iron was given as the chelate.

Since both oral and parenteral modes of administration appear to have some degree of therapeutic value, a combination of these two routes would seem to be worthy of attention. The only experimental evidence that we have been able to find relevant to this approach is provided by Whitten et al, who have shown a marked increase in survival in dogs that had been treated with combined oral and IV deferoxamine in spite of the lack of protection afforded by either method alone.[3,19]

ADJUNCTIVE THERAPY

Various modes of adjunctive therapy have also been advocated without good experimental data to show clinical efficacy. Bicarbonate will form insoluble aggregates of ferrous carbonate and impede iron absorption from physiologic doses of iron in man.[17] The $NaHCO_3$, given either orally or intraperitoneally, greatly decreased mortality in mice when compared with untreated controls.[57] Oral phosphates (eg, sodium biphosphate) have also been advocated on the basis that they, too, will form insoluble aggregates.[4] Although this decreases the absorption after small doses of iron, its effectiveness has never been demonstrated after toxic doses.

Exchange transfusion has been suggested as a method for the enhancement of iron elimination.[46] In view of the rapid intracellular movement of iron, exchange transfusion would not seem to be an efficient therapeutic modality. The single study, in our search of the literature, of exchange transfusion in iron poisoning (in dogs) has documented the inefficiency of this maneuver.[46] If the pathophysiologic effect of iron poisoning involves the generation of free radicals initiated by ferrous ions, then it might be possible to aim therapy at the systems involved in the initiation and propagation of free radicals and lipid peroxidation. One might provide an antioxidant or a free-radical scavenger such as vitamin E, ethoxyquin, or a sulfhydryl-containing agent such as penicillamine or mercaptamine (cysteamine). Remarkably similar morphologic changes have been found in both vitamin E-deficient and iron-overloaded animals.[58,59] At a biochemical level, many of the abnormalities of cellular respiration found in iron-poisoned mitochondria are also found in mitochondria from vitamin E-deficient animals. The addition of vitamin E to these in vitro preparations reverses the iron-induced morphologic abnormalities and restores the normal respiratory control.[24,25,34] Furthermore, vitamin E-deficient animals show a markedly enhanced susceptibility to iron poisoning,[60,61] and chronically iron-poisoned animals that are treated with large doses of vitamin E have demonstrated prevention of some pathologic changes.[62-64] Two patients with iron poisoning were allegedly successfully treated with vitamin E in 1951.[65] We emphasize that we are not advocating the use of antioxidants or sulfhydryl-containing compounds for iron poisoning but merely raising these possibilities as speculations.

RECOMMENDATIONS

Based on the information just reviewed, our belief is that a rational therapeutic approach to acute iron poisoning is possible (Table). While recognizing that mortality and substantial morbidity are infrequent in comparison with the total number of patients with a history of iron ingestion, we believe that the initial management suggested is justified in view of the potential seriousness of this poisoning.

All patients arriving with a history of iron ingestion should be given an IM injection of 2 g of deferoxamine mesylate. Emesis with ipecac should be immediately induced if the patient is conscious and a gag reflex is present. The vomitus should be examined for evidence of iron tablets. After emesis, gastric lavage should be performed with a solution containing 2 g of deferoxamine mesylate per liter of water and sufficient $NaHCO_3$ to alkalinize ($pH > 5$) the gastric contents and increase the deferoxamine complexation of iron.[66] After lavage, deferoxamine mesylate (10 g in 50 mL of water; a dose that should complex a substantial percentage of most ingestions in small children) should be left in the stomach with sufficient $NaHCO_3$ added so that the aspirated gastric contents will have a pH greater than 5. This is easily checked with pH paper.

An elevated total serum or plasma

Treatment of Iron Poisoning for All Patients With a History of Excessive Iron Ingestion

A. Perform the following:
   1. Give deferoxamine (2 g intramuscularly, unless the patient is in shock)
   2. Give ipecac (if patient is conscious and if gag reflex is present)
   3. Lavage (after emesis) with deferoxamine (2 g in 1 L of water containing enough $NaHCO_3$ to "alkalinize" [pH > 5] the gastric contents)
   4. Leave in stomach (via lavage tube) deferoxamine (10 g in 50 mL of water with sufficient $NaHCO_3$ to alkalinize [pH > 5] the gastric contents)
   5. Provide intravenous (IV) fluids as necessary
   6. Obtain a serum iron level
   7. Obtain an abdominal roentgenogram

B. Consider the following three conditions and initiate action as follows (C, D):
   1. Signs or symptoms by history or observation
   2. *Vin rosé*-colored urine with good urine output
   3. Evidence of iron tablets by adbominal roentgenogram

C. If all three conditions are negative for six hours of observation, then discharge after six hours

D. If any of the three conditions is positive, then admit for further treatment as follows:
   1. Give deferoxamine by continuous IV infusion (15 mg/kg/hr)
   2. Monitor and support intravascular volume and tissue perfusion
   3. Continue therapy until urine is clear of *vin rosé* color and patient is asymptomatic for at least 24 hours
   4. Discharge patient
   5. Perform follow-up examination

iron level can be a useful index of significant ingestion. However, it is important to reemphasize that, due to the rapid clearance of free iron, severely toxic conditions can be associated with only minimally elevated plasma iron levels.[2,5,10,13] In animal studies with LDs of oral iron, the serum iron level one hour after ingestion ranged from 800 to 13,800 μg/dL.[3] When serial serum iron levels were studied, death was usually associated with peak serum iron levels over 1,000 μg/dL, but it was also associated with serum iron levels less than 500 μg/dL as early as three hours after ingestion.[10] Peak serum iron levels usually occur between two and four hours after ingestion.[3,12,20] Clinical reports have also included instances of serious toxicity with serum iron levels below 300 μg/dL.[2,3,10] In view of these data, whereas it seems reasonable that a serum iron level over 300 μg/dL should be of concern, a level less than 300 μg/dL does not rule out serious intoxication. It is important to remember that colorimetric methods for determining serum iron levels can give falsely low values in the presence of deferoxamine[67] unless a strong reducing agent is added to the assay system.[68]

Fluids should be given to ensure a good urinary output and any urine passed should be observed for a *vin rosé* color, which indicates iron as ferrioxamine that has been filtered into the urine. The initial urine obtained may reflect residual urine formed prior to the administration of the deferoxamine and thus may be negative in the face of a serious ingestion.

A roentgenogram of the abdomen may be useful in detecting evidence of residual iron tablets.

If, six hours after ingestion, the patient remains asymptomatic by history and observation; there is a good urinary output with absence of any *vin rosé* color; and the abdominal roentgenogram does not show residual iron tablets, then it is likely that the patient can be safely sent home.

The child who at any time, by history or observation, is considered to exhibit signs or symptoms of acute iron poisoning (see "Clinical Description"), passes a *vin rosé*-colored urine, or has an abnormal abdominal roentgenogram for iron tablets should be started on a continuous IV infusion of deferoxamine at 15 mg/kg/hr in either saline or lactated Ringer's solution. In view of the possible intracellular action of deferoxamine, it seems reasonable to continue treatment until after the *vin rosé* color of the urine has been clear and the child is without signs or symptoms of iron poisoning for 24 hours. In the event of ingestion of enteric coated tablets and/or an abnormal abdominal roentgenogram, even though the urine is initially clear, it is probably safest to continue IV deferoxamine for 24 hours.

In addition to the above recommendations, we cannot stress too strongly the importance of careful monitoring and vigilance in maintaining optimal intravascular volume and tissue perfusion. In the markedly symptomatic child, particular attention should be paid to adequately replacing "third space" fluid losses. In our experience with significant iron intoxications both in children and in animal studies, large volumes of colloid and crystalloid replacement are necessary to maintain perfusion to critical organ beds. With large GI losses that may not be immediately appreciated, the child who is clinically manifesting any marked signs of a toxic condition deserves immediate admission to an intensive care unit. Placement of adequate catheters for monitoring and for infusion, as would be done in any patient at considerable risk of shock, should be carried out immediately. A separate IV line should be established specifically for deferoxamine administration so that fluid boluses can be given without fear of rapidly infusing deferoxamine.

In the unfortunate child who, despite optimal support and management, manifests oliguria or anuria as associated with shock or coma, thereby indicating a severe intoxication, hemodialysis should be considered while continuing IV deferoxamine in view of ferrioxamine's ability to be dialyzed.[19] Peritoneal dialysis in the face of shock or hypoperfusion would likely be ineffective.

In those children who experience acute iron poisoning, it is important to plan adequate follow-up for the potential sequelae outlined previously. Additionally, there may occur the paradox of iron deficiency anemia after acute iron poisoning (oral communication, William H. Zinkham, MD, December 1963). This may reflect a combination of GI losses and chelation of iron stores by deferoxamine.

Finally, we wish to emphasize that an ounce of prevention is worth more than a pound of deferoxamine.

William H. Zinkham, MD, provided thoughtful criticism, and Evelyn Fleckenstein, provided secretarial assistance, in the preparation of this report.

You can help
the ADD* child
with Cylert
(pemoline)
SCHOOL NURSE

Day-long behavior therapy without dosing problems at school

Impressive all-day control.

Cylert works extremely well, given an adequate period of trial. Single daily doses are as effective for behavior control as multiple doses of methylphenidate or amphetamines. Blood levels are well sustained, without necessity for multidose administration.

No troublesome midday dose.

Cylert avoids problems of taking a drug at school. No involvement of school personnel. No peer teasing about noon-time dosing. The parents manage all medication, and the child carries no drugs. (And note that Cylert is Schedule IV, not II.)

Cylert® (pemoline) **C IV**

18.75, 37.5, 75 mg tablets; 37.5 mg chewables

Just once a day. At home.

*ADD: Attention Deficit Disorder (formerly called MBD, Minimal Brain Dysfunction), or the Hyperkinetic Syndrome. Please see next page for Brief Summary.

ABBOTT

Cylert® (pemoline)

DESCRIPTION: CYLERT (pemoline) is a central nervous system stimulant. Pemoline is structurally dissimilar to the amphetamines and methylphenidate.

It is an oxazolidine compound and is chemically identified as 2-amino-5-phenyl-2-oxazolin-4-one.

Pemoline is a white, tasteless, odorless powder, relatively insoluble (less than 1 mg./ml.) in water, chloroform, ether, acetone, and benzene; its solubility in 95% ethyl alcohol is 2.2 mg./ml.

CYLERT (pemoline) is supplied as tablets for oral administration.

CLINICAL PHARMACOLOGY: CYLERT (pemoline) has a pharmacological activity similar to that of other known central nervous system stimulants; however, it has minimal sympathomimetic effects. Although studies indicate that pemoline may act in animals through dopaminergic mechanisms, the exact mechanism and site of action of the drug in man is not known.

There is neither specific evidence which clearly establishes the mechanism whereby CYLERT produces its mental and behavioral effects in children, nor conclusive evidence regarding how these effects relate to the condition of the central nervous system.

The serum half-life of pemoline is approximately 12 hours. Peak serum levels of the drug occur within 2 to 4 hours after ingestion of a single dose. Multiple dose studies in adults at several dose levels indicate that steady state is reached in approximately 2 to 3 days.

Metabolites of pemoline include pemoline conjugate, pemoline dione, mandelic acid, and unidentified polar compounds. CYLERT is excreted primarily by the kidneys; approximately 75% of an oral dose is recovered in the urine within 24 hours. Approximately 43% of pemoline is excreted unchanged.

CYLERT (pemoline) has a gradual onset of action. Using the recommended schedule of dosage titration, significant clinical benefit may not be evident until the third or fourth week of drug administration.

INDICATIONS: CYLERT is indicated as an integral part of a total treatment program which typically includes other remedial measures (psychological, educational, social) for a stabilizing effect in children with a behavioral syndrome characterized by the following group of developmentally inappropriate symptoms: moderate to severe distractibility, short attention span, hyperactivity, emotional lability, and impulsivity. The diagnosis of this syndrome should not be made with finality when these symptoms are only of comparatively recent origin. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of central nervous system dysfunction may or may not be warranted.

Attention Deficit Disorder and Hyperkinetic Syndrome are among the terms being used to describe the above signs and symptoms. In the past, a variety of terms has been associated with these signs and symptoms, including: Minimal Brain Dysfunction, Hyperkinetic Reaction of Childhood, Hyperkinetic Syndrome, Hyperactive Child Syndrome, Minimal Brain Damage, Minimal Cerebral Dysfunction, and Minor Cerebral Dysfunction.

CONTRAINDICATIONS: CYLERT (pemoline) is contraindicated in patients with known hypersensitivity or idiosyncrasy to the drug. (See ADVERSE REACTIONS.)

WARNINGS: CYLERT is not recommended for children less than 6 years of age since its safety and efficacy in this age group have not been established.

Clinical experience suggests that in psychotic children, administration of CYLERT may exacerbate symptoms of behavior disturbance and thought disorder.

Data are inadequate to determine whether chronic administration of CYLERT may be associated with growth inhibition; therefore, growth should be monitored during treatment.

PRECAUTIONS: Drug treatment is not indicated in all cases of the behavioral syndrome characterized by moderate to severe distractibility, short attention span, hyperactivity, emotional lability and impulsivity. It should be considered only in light of the complete history and evaluation of the child. The decision to prescribe CYLERT should depend on the physician's assessment of the chronicity and severity of the child's symptoms and their appropriateness for his/her age. Prescription should not depend solely on the presence of one or more of the behavioral characteristics.

When these symptoms are associated with acute stress reactions, treatment with CYLERT is usually not indicated.

Long-term effects of CYLERT in children have not been well established.

Liver function tests should be performed prior to and periodically during therapy with CYLERT. The drug should be discontinued if abnormalities are revealed and confirmed by follow-up tests. (See ADVERSE REACTIONS regarding reports of abnormal liver function tests and jaundice.)

CYLERT should be administered with caution to patients with significantly impaired hepatic or renal function.

The interaction of CYLERT with other drugs has not been studied in humans. Patients who are receiving CYLERT concurrently with other drugs, especially drugs with CNS activity, should be monitored carefully.

CYLERT failed to demonstrate a potential for self-administration in primates. However, the pharmacologic similarity of pemoline to other psychostimulants with known dependence liability suggests that psychological and/or physical dependence might also occur with CYLERT. There have been isolated reports of transient psychotic symptoms occurring in adults following the long-term misuse of excessive oral doses of pemoline. CYLERT should be given with caution to emotionally unstable patients who may increase the dosage on their own initiative.

Usage during Pregnancy and Lactation: The safety of CYLERT (pemoline) for use during pregnancy and lactation has not been established.

Studies in rats have shown an increased incidence of stillbirths and cannibalization when pemoline was administered at a dose of 37.5 mg./kg./day. Postnatal survival of offspring was reduced at doses of 18.75 and 37.5 mg./kg./day.

ADVERSE REACTIONS: Insomnia is the most frequently reported side effect of CYLERT; it usually occurs early in therapy, prior to an optimum therapeutic response. In the majority of cases it is transient in nature or responds to a reduction in dosage.

Anorexia with weight loss may occur during the first weeks of therapy. In the majority of cases it is transient in nature; weight gain usually resumes within three to six months.

Stomach ache, skin rashes, increased irritability, mild depression, nausea, dizziness, headache, drowsiness, and hallucinations have been reported.

Elevations of SGOT, SGPT, and serum LDH have occurred in patients taking CYLERT, usually after several months of therapy. These effects appear to be reversible upon withdrawal of the drug, and are thought to be manifestations of a delayed hypersensitivity reaction. There have also been a few reports of jaundice occurring in patients taking CYLERT; a causal relationship between the drug and this clinical finding has not been established.

The following CNS effects have been reported with the use of CYLERT: dyskinetic movements of the tongue, lips, face and extremities, nystagmus and nystagmoid eye movements, and convulsive seizures. A definite causal relationship between CYLERT and these reactions has not been established.

Mild adverse reactions appearing early during the course of treatment with CYLERT often remit with continuing therapy. If adverse reactions are of a significant or protracted nature, dosage should be reduced or the drug discontinued.

OVERDOSAGE: Signs and symptoms of acute CYLERT overdosage may include agitation, restlessness, hallucinations, dyskinetic movements and tachycardia. The treatment for an acute overdosage of pemoline is essentially the same as that for an overdosage of any CNS stimulant. Management is primarily symptomatic and may include induction of emesis or gastric lavage, sedation, and other appropriate supportive measures.

Results of studies in dogs indicate that extracorporeal hemodialysis may be useful in the management of CYLERT overdosage; forced diuresis and peritoneal dialysis appear to be of little value.

DOSAGE AND ADMINISTRATION: CYLERT (pemoline) is administered as a single oral dose each morning. The recommended starting dose is 37.5 mg./day. This daily dose should be gradually increased by 18.75 mg. at one week intervals until the desired clinical response is obtained. The effective daily dose for most patients will range from 56.25 to 75 mg. The maximum recommended daily dose of pemoline is 112.5 mg.

Clinical improvement with CYLERT is gradual. Using the recommended schedule of dosage titration, significant benefit may not be evident until the third or fourth week of drug administration.

Where possible, drug administration should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued therapy.

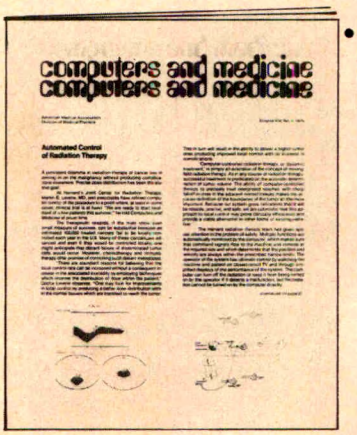
COMPUTERS AND MEDICINE



This bi-monthly publication is an invaluable source of information on the latest developments in medical computing technology. Produced by the AMA Computers Systems in Medicine Program, **Computers and Medicine** reports on the ways computer technology is used clinically and adminstratively in private practices, hospitals, clinics, and medical societies.

The format of **Computers and Medicine** emphasizes brief articles which convey the fundamental concepts involved in applications currently in use, as well as those in developmental and experimental stages.

Denouement and Discussion

Hemifacial Atrophy (Romberg's Syndrome)

Fig 1.—Characteristic facial appearance with atrophy limited to one side.

Fig 2.—Brown pigmentation and sparsity of hair on same side as atrophy.

Fig 3.—Hemiatrophy of tongue that is deviated toward facial lesion.

Manifestations

Major manifestations include progressive atrophy of the face accompanied by seizures, trigeminal neuralgia, and increased pigmentation of the overlying skin.

The atrophy involves skin, subcutaneous tissue, muscles, and occasionally cartilage and bone. It usually appears by age 10 and, initially, frequently involves the temporal or buccinator muscles; it then extends to the brow, angle of the mouth, neck; and subsequently it may involve other parts of the body. The left side is more frequently affected than the right. The atrophy continues for approximately three years and then becomes nonprogressive. Changes in the hair may precede the skin findings and include alopecia and poliosis. Eye abnormalities, frequently secondary to the atrophy, may occur and consist of enophthalmos, outward slanting of the outer canthus, muscular paralyses, inflammation of the eyes, heterochromia of the iris, and Horner's syndrome.

Epilepsy, mainly of the Jacksonian type, is a common neurologic occurrence and usually appears late. Trigeminal neuralgia and migraine headaches also occur.

Roentgenograms of the jaw show the bodies of the ramus and mandible to be shorter on the affected side. The teeth on the involved side may be delayed in erupting and have atrophic roots.

Differential diagnosis includes scleroderma, fat necrosis, hemifacial microsomia, and oculoauriculovertebral dysplasia (Goldenhar's syndrome).

Genetics

The majority of cases have been sporadic although there have been a few familial cases reported. A history of facial trauma has been reported in some affected individuals.

Treatment

Since it is a self-limiting condition, treatment is mainly symptomatic. Plastic surgery is frequently helpful.

Radiological Case of the Month

Lionel W. Young, MD; Contributed by Kong Meng Tan, MD

A17-year-old high school football player complained of pain involving his left hip after a game. He was referred to the orthopedic department, Kaiser-Permanente Medical Center, Richmond, Calif, after roentgenograms (anteroposterior pelvis, Fig 1) of his left hip had been reviewed by the radiologist and the boy's pediatrician. He had no previous complaints or hospital admissions. No laboratory examinations were obtained.

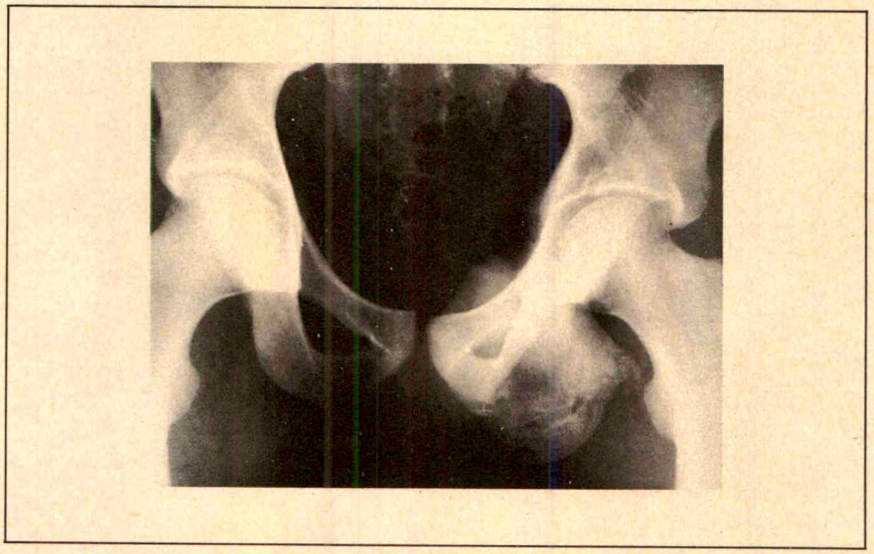

Figure 1.

From the Department of Radiology, Kaiser-Permanente Medical Center, Richmond, Calif.

Denouement and Discussion

Traumatic Ischial Apophyseolysis

Fig 1.—Anteroposterior roentgenogram of pelvis. Large bony mass inferior to and replacing most of left ischial tuberosity is seen. Note radiolucent line of nonunion that, when present, is diagnostic of incompletely healed avulsion of ischial apophysis.

Fig 2.—Anteroposterior roentgenogram of pelvis made three years earlier shortly after acute injury shows moderate separation of crescent-shaped left ischial apophysis.

The roentgenographic appearance was pathognomonic for traumatic avulsion of the left ischial apophysis with subsequent exuberant callus reaction. Three years prior to the present injury, the patient was injured during basketball practice. At that time, he noted a sudden, severe pain in his left buttock. Roentgenograms showed a traumatic avulsion of the left ischial apophysis (Fig 2). The pain gradually subsided during the next several months. At the time of his second injury, the mass was palpable on careful examination but caused no discomfort despite its size. Slight functional disability, mainly an inability to fully flex his left knee, was noted. No treatment was undertaken.

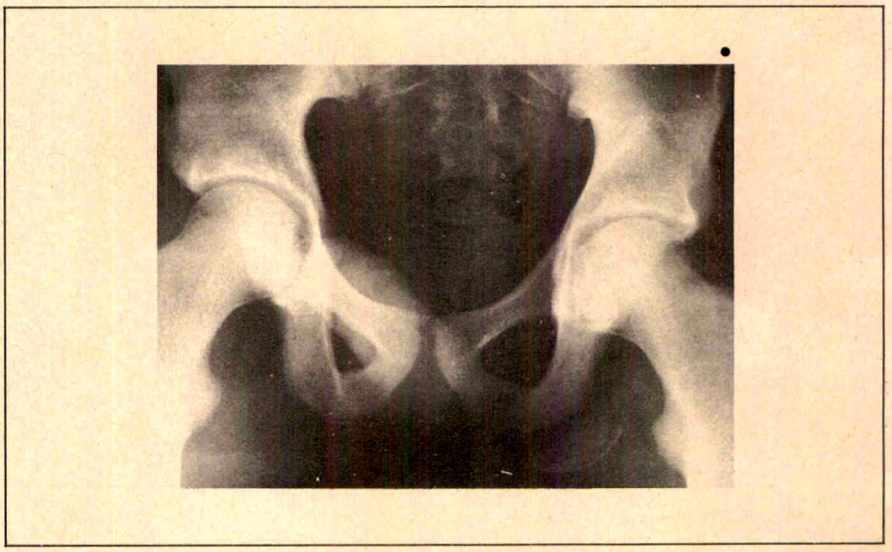

Figure 2.

Avulsion fracture of the ischial tuberosity is a rare but well-known clinical entity. This occurs typically between puberty and 25 years of age and relates to the time of appearance of the secondary ossification center and its fusion to the ischial tuberosity.[1] Avulsion results from sudden, vigorous pull of the hamstring muscle group and is found mainly in athletes, dancers, cheerleaders, and others engaged in similar activities.

The entity is of interest because the exuberant bony overgrowth following healing can cause it to be mistaken for a malignant neoplasm.[2,3] In two of previously reported cases, excision of the mass was performed because of the strong suspicion of malignant neoplasm.

Recognition of the lesion is, therefore, important. Radical surgical therapy such as amputation or hemipelvectomy can be avoided if a careful clinical history is obtained and the roentgenographic findings are carefully scrutinized. Often, previous roentgenograms showing the avulsed apophysis as a small crescentic rim of bone (Fig 2) are available for comparison. A characteristic follow-up finding is a well-delineated radiolucent line of nonunion that is usually found in two thirds of all cases.[3]

The differential diagnosis may include myositis ossificans, calcified hematoma, osteochondroma, enchondroma, or chondrosarcoma. Treatment is usually conservative, with no serious sequelae, though Schlonsky and Olix[4] have reported two cases that had persistent functional disability after conservative therapy. They recommend open reduction and fixation in cases in which the apophysis is widely separated.

Barnes and Hinds[3] found less than 40 cases of avulsion of the ischial apophysis reported in the English literature. In their analysis, they observed that 68% of the avulsions did not unite and that ten of the 14 cases treated surgically were late excisions of the mass mainly because of pain.

Announcing . . . An important new publication on Physician Well-Being!

An invaluable guide for:

- **Residents • Medical Students**
- **Faculty members**
- **Residency Program Directors**
- **Members of Medical Society Impaired Physician Committees**

Beyond Survival is the first concise guide on how to establish and operate programs for helping colleagues with problems and enriching professional and family life during the training years.

Produced by the Work Group on Physician Well-Being, Resident Physician Section, American Medical Association, *Beyond Survival* draws upon experience from self-help efforts in several parts of the country, and offers a range of examples of successful intervention techniques.

Major sections are devoted to identification, treatment, and rehabilitation procedures for cases where problems have already developed, and methods of promoting well-being and preventing disorders from occurring in later life.

A review of the current literature, an annotated bibliography, and a listing of national and state medical society resources are also included.

HOW TO FIX

A FOUR-STEP BLUEPRINT

STEP 1.

INVITE 150 PRACTICING PHYSICIANS TO TALK ABOUT PEDIATRIC COUGH/COLD LIQUIDS.

THEN, LISTEN TO THEIR COMPLAINTS.

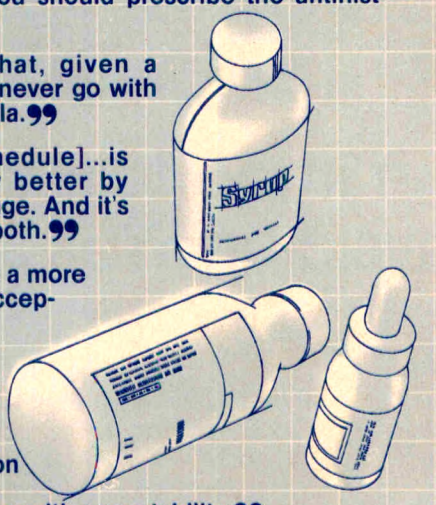
Sometimes a revolution begins by simply taking the obvious first step. Bristol Laboratories conducted a series of interviews and panel discussions with 150 physicians having active pediatric practices in all parts of the country.

Here are some of the comments heard most frequently:

"...they've had too many mixtures. If you want an antihistamine, you should prescribe the antihistamine plain."

"I've decided that, given a choice, I would never go with a narcotic formula."

"[A dosage schedule]...is really probably better by weight than by age. And it's helpful to have both."



"If you can, make a more concentrated, acceptable solution... higher doses of drug are more effective."

"...expectoration and decongestion are my prime objectives—along with acceptability."

"Pseudoephedrine is a stimulant. I don't think it's a good idea in infants under two years."

"[When treating very young children,] you don't want to suppress the cough."

"I do not prescribe codeine for small children. I prefer dextromethorphan."

"I think the taste factor is also important...so do the mothers!"

BRISTOL™

Division of Bristol-Myers Company
Syracuse, New York 13201

STEP 2.

RECOGNIZE THAT WHAT *ISN'T* PUT PEDIATRIC COUGH/COLD LIQUIDS IS JUST AS IMPORTANT AS WHAT

Depending on patient age, these components regarded as undesirable by most of the physic consulted:

FOR INFANTS
No cough suppressant to interfere with expectoration of mucus.

FOR INFANTS & CHILDREN
No antihistamine to produce excessive drying side effects. Antihistamines are counterproductive to the mucous-liquifying action of expectorants.

FOR INFANTS & CHILDREN
No pseudoephedrine, with its assoc higher incidence of CNS side effects.

FOR INFANTS & CHILDR
No codeine or other narcotic d atives.

FOR INFANTS & CHILDREN
No subtherapeutic formulations, ri treatment failure or necessitating incre dosage.

INTRODUCIN

KIDS' COUGHS.
ATIONAL SYMPTOMATIC THERAPY.

STEP 3.

Y, DESIGN A SIMPLE, HIGH-POTENCY NFANT COUGH/COLD FORMULA.

(BEFORE PROCEEDING, REVIEW STEP 1.)

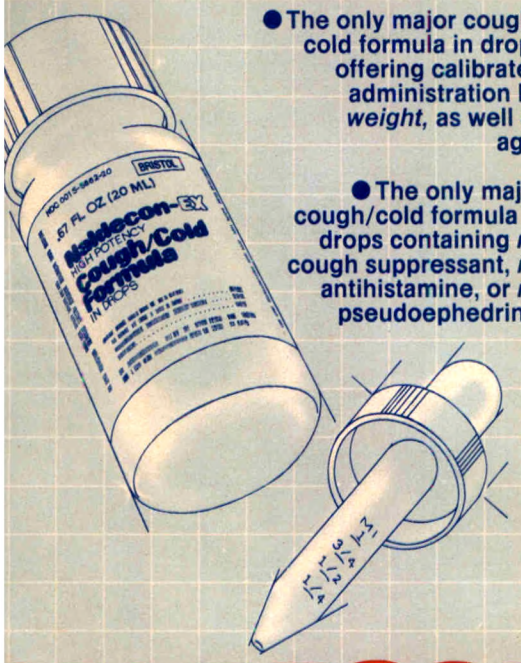
ch 1 ml dropperful contains:

enylpropanolamine HCl . . . . . 9 mg
aifenesin (glyceryl guaiacolate) . . . . . 30 mg
ohol 0.6%

r symptomatic relief of coughing and nasal d bronchial congestion due to colds, flu, bron- tis and croup.

e only major cough/cold formula in drops based) mg of expectorant action (guaifenesin) to en- ge productive coughing.

e only major cough/cold formula in drops includ- henylpropanolamine, a decongestant with mini- CNS side effects.



- The only major cough/cold formula in drops offering calibrated administration by *weight*, as well as age.
- The only major cough/cold formula in drops containing *no* cough suppressant, *no* antihistamine, or *no* pseudoephedrine!

STEP 4.

NEXT, DEVELOP A HIGH-POTENCY COUGH/COLD PRODUCT FOR AGES 2 TO 12.

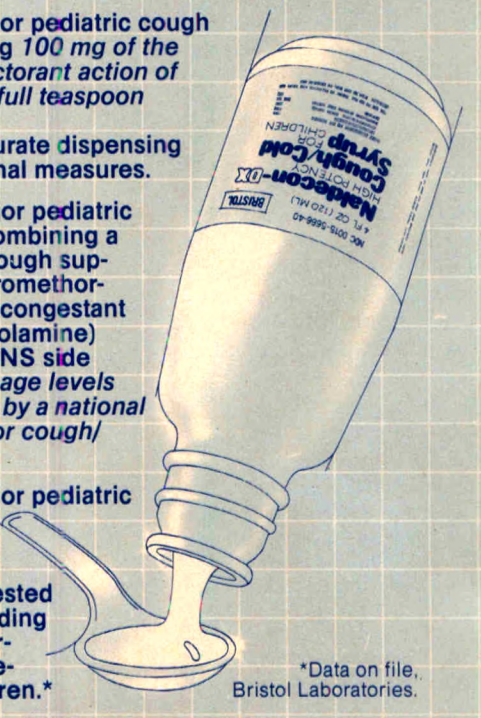
(REFER TO SPECIFICATIONS IN STEP 1.)

Each teaspoonful (5 ml) contains:

Phenylpropanolamine HCl . . . . . 9 mg
Dextromethorphan hydrobromide . . . . . 7.5 mg
Guaifenesin (glyceryl guaiacolate) . . . . . 100 mg
Alcohol 5%

For symptomatic relief of coughing and nasal and bronchial congestion due to colds or flu.

- The only major pediatric cough syrup delivering *100 mg of the powerful expectorant action of guaifenesin in full teaspoon doses.* —insuring accurate dispensing without fractional measures.
- The only major pediatric cough syrup combining a non-narcotic cough suppressant (dextromethorphan) and a decongestant (phenylpropanolamine) with minimal CNS side effects—*at dosage levels recommended by a national review panel for cough/cold products.*
- The only major pediatric cough syrup with the great Naldecon fruit flavor—taste-tested against the leading brand and overwhelmingly preferred by children.*



*Data on file, Bristol Laboratories.

- And, Naldecon-DX contains *no* codeine and *no* antihistamine!

NALDECON-EX™ DROPS
NALDECON-DX™ SYRUP

THE PRACTITIONERS' COUGH FIXERS

Clinical Memoranda

Unilateral Thyroid Enlargement With Hyperthyroidism

Single thyroid nodules are rare in childhood and adolescence. These nodules may be nonfunctioning, as is the case for the majority of benign adenomas,[1] or functioning. Functioning thyroid nodules may be nonautonomous[2] or autonomous. Data on the occurrence of autonomous thyroid nodules are scarce. Autonomous nodules function independently of the pituitary-thyroid axis; they do not respond to thyroid-stimulating hormone (TSH) nor are they suppressed by thyroxine therapy.[3] Such nodules have been reported in both euthyroid[4-7] and hyperthyroid individuals.[1,8-12] The term "toxic adenoma" describes only the latter group of patients.

The purpose of this report is to describe two girls who had hyperthyroidism and unilateral thyroid enlargement and in whom no other thyroid tissue could be palpated. The first patient had a toxic adenoma of the thyroid gland, whereas the second patient had Graves' disease with congenital absence of the contralateral lobe. The similar clinical presentation of these two patients illustrates difficulties that may be encountered in the evaluation of functioning thyroid nodules.

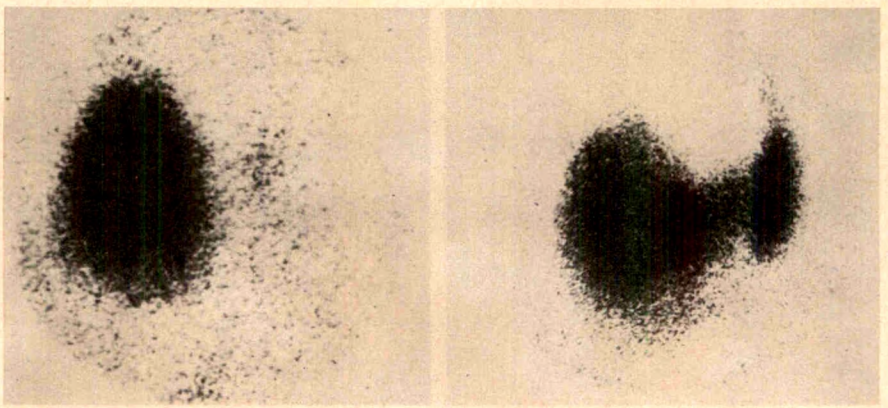
Report of Cases.—CASE 1.—A 6-year-old girl with a four-month history of hyperactivity, distractibility at school, heat intolerance, emotional lability, tremor, and restless sleeping was seen by her family pediatrician. There was no history of thyroid disease in the family. A smooth, firm, symmetrical, right-sided goiter was noted measuring 4 × 3 cm. The pulse rate was 130 beats per minute, blood pressure was 100/40 mm Hg, height was 129 cm (95th percentile), and weight was 22.5 kg (50th percentile). There was no exophthalmos or lid lag. The serum thyroxine (T_4) level was 17 μg/dL (normal, 5.6 to 12.6 μg/dL); serum TSH level was 2 μμ/mL (normal, < 10 μμ/mL); triiodothyronine (T_3) resin uptake was 42% (normal, 25% to 35%); uptake of ^{131}I at four hours was 23% (normal, 3% to 14%) and at 24 hours was 32% (normal, 6% to 29%). A technetium thyroid scan demonstrated a hot nodule in the right lobe (Fig 1) with no uptake in the left lobe. After propylthiouracil treatment (200 mg four times a day) for 2½ months, she was referred to us, at which time symptoms of hyperthyroidism had regressed and the serum T_4 level was 2.8 μg/dL and the serum TSH level was 50 μμ/mL. A repeated technetium thyroid scan was performed that again showed the nodule on the right but, in addition, considerable uptake in the left lobe (Fig 1). The patient had surgery and a 4 × 3-cm adenoma involving the right lobe of the thyroid was removed; the left lobe of the thyroid at time of surgery appeared normal. Subsequent to surgery, and without receiving medication, she is clinically and biochemically euthyroid.

CASE 2.—A 5-year-old girl had a six-month history of fidgetiness, tremor, increased frequency of bowel movements, insomnia, and accelerated linear growth. There was no family history of thyroid disease. On physical examination, exophthalmos and lid lag were present. There was a smooth, firm, symmetrical left-sided goiter measuring 2.5 × 3 cm; thyroid tissue could not be palpated on the right side of the neck. There was no bruit over the goiter. In addition, a gross tremor of the fingers and hands was noted, the palms were moist, the pulse rate was 130 beats per minute, blood pressure was 110/50 mm Hg, a grade 2/6 ejection systolic murmur was present along the left sternal border, the height was 122 cm (2 cm above the 97th percentile), and weight was 17.5 kg (40th percentile). The serum T_4 level was 16 μg/dL, T_3 resin uptake was 42%, and serum TSH level was less than 2 μμ/mL. Uptake of ^{131}I was 48% at two hours and 73% at 24 hours. A technetium TC 99m thyroid scan showed uniform increased uptake on the left but no uptake on the right (Fig 2). After propylthiouracil therapy (5 mg/kg/24 hr in three divided doses), the patient became euthyroid but subsequently fever, rash, arthritis, and leukopenia developed that necessitated discontinuation of drug therapy. When the drug therapy was discontinued, the patient had an exacerbation of hyperthyroidism that was then successfully treated with radioactive sodium iodide I 131; a total of 18 mCi of radioactive iodine was given in three doses during a 15-month period. (A TSH stimulation test performed when the patient was euthyroid was discontinued after one injection of bovine TSH, 5 IU, because of untoward side effects.) At present, she is clinically and biochemically euthyroid (serum TSH, 5 μμ/mL; T_4, 6.9 μg/dL) without therapy one year after her last radioactive iodine treatment.

Comment.—In 1956, Hayles and associates[1] described the first case of childhood toxic adenoma in a 7-year-old girl. The diagnosis was confirmed histologically. Since then, ten cases of autonomous single thyroid nodules in children have been reported. Five of these occurred in euthyroid patients[4-7]; the remaining five[8-12] as well as the patient described by Hayles et al[1] had associated hyperthyroidism. Molnar et al[13] suggested that clinical toxicity does not appear until the nodule is at least 3 cm in diameter. However, patients with large autonomous nodules may remain euthyroid.[14] All patients with toxic adenoma had biochemical evidence of hyperthyroidism; three had elevated T_3 levels[8,9,11] and Popma et al[8] suggest that T_3 may be preferentially secreted by toxic adenomata. Although the demonstration of function in a nodule largely excludes a malignant diagnosis,[15] thyroid carcinoma causing hyperthyroidism has been described.[16]

It is difficult to clinically differentiate toxic adenoma from Graves' disease involving one lobe of the thyroid gland with congenital absence of the contralateral lobe. In general, patients with toxic adenoma have milder and fewer toxic symptoms than do pa-

Fig 1.—Thyroid scan of case 1 before (left) and after (right) propylthiouracil treatment. Note uptake in both lobes after propylthiouracil reflecting thyroid-stimulating hormone effect (case 1).



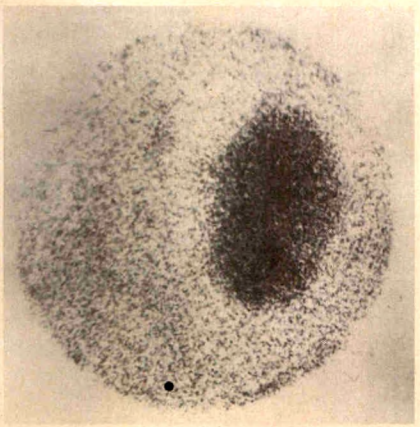


Fig 2.—Thyroid scan of case 2 showing diffuse increased uptake of radioisotope on left side with absence of uptake on right side (case 2).

tients with Graves' disease. Plummer emphasized lack of ocular changes as the most important clinical feature differentiating toxic adenoma from Graves' disease in adults.[7] Having reviewed the childhood cases of toxic adenoma, we believe that the same phenomenon is true in children. The presence of exophthalmos and lid lag in our second patient suggested the diagnosis of Graves' disease. The diagnosis was established by thyroid scan that showed generalized thyroid enlargement on the left side and absence of any thyroid tissue on the right. When the diagnosis of Graves' disease with congenital absence of one lobe is in doubt, one can determine serum levels of thyroid-stimulating immunoglobulin[17] and perform a TSH stimulation test followed by a ^{99m}Tc thyroid scan.[10] Results of the former test will usually be positive in Graves' disease and the latter test will show absence of any thyroid tissue on the contralateral side after TSH stimulation.

Hydrops of the Gallbladder

Hydrops of the gallbladder is an uncommon problem in infants and children. Most cases of hydrops of the gallbladder previously reported are seen as a complication of other illnesses, such as upper respiratory tract infections, salmonellosis, cervical adenitis, and pseudomonas sepsis in children with severe burns and diarrhea. Hydrops has also been associated with systemic infections caused by leptospirosis and group A streptococcal infection as scarlet fever.[1-3] We report a neonate with group B streptococcal sepsis and pneumonia in whom gallbladder hydrops developed that completely resolved without further complications after seven days of antibiotic therapy.

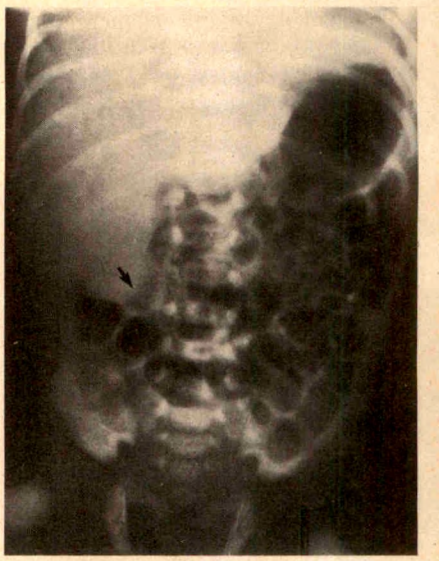

Fig 1.—Plain film of abdomen showing soft-tissue mass density (arrow) extending caudad from liver edge in right upper abdominal quadrant.

Report of a Case.—The patient is a 3,240-g, term male infant born to a 34-year-old mother after an uncomplicated pregnancy and delivery. At 8 hours of age, progressive respiratory distress, fever to 40 °C, and hypotension developed. Roentgenograms of the chest demonstrated diffuse infiltrates in both lung fields. Respiratory decompensation, shock, and acidosis were managed with assisted ventilation, transfusion of whole blood, bicarbonate, and intravenous (IV) dopamine infusion. Cultures were obtained and IV ampicillin sodium and gentamicin sulfate therapy were started.

By the third day of life, when the initial respiratory distress and shock were resolving, a palpable mass was noted in the right upper quadrant of the abdomen, as well as a well-defined roentgenographic density in the same location (Fig 1). Abdominal distension and generalized edema also developed at this time. Real-time ultrasonography of the abdomen, using a 7.4-mHz linear array system, demonstrated a dilated gallbladder without evidence of calculi or intrahepatic biliary obstruction (Fig 2). Necrotizing enterocolitis was also suspected and oral feeding was discontinued. Intermittent nasogastric suction was started and the abdominal distension resolved within 24 hours.

Cultures of the blood, gastric aspirate, and external ear canal obtained at admission grew group B β-hemolytic streptococcus. A second abdominal ultrasound study four days after the initial study showed resolution of the hydrops (Fig 3). Intravenous antibiotic therapy was continued for two weeks and the baby was discharged in good condition at 3 weeks of age.

Comment.—Acute distension of the

gallbladder is very uncommon during the neonatal period. Among the cases in infants reported by Bloom and Swain,[2] anatomic obstruction to the cystic duct was the usual predisposing factor. Two cases of acute cholecystitis due to *Str viridans*[4] and *Escherichia coli*[5] have been reported in infants less than 3 weeks old. Robinson et al[6] described three cases of hydrops of the gallbladder in neonates due to group B β-hemolytic streptococcus, *Serratia marcescens*, and α-streptococcus. Surgery was performed on all three.

However, spontaneously resolving hydrops of the gallbladder in the neonatal period has not been described.

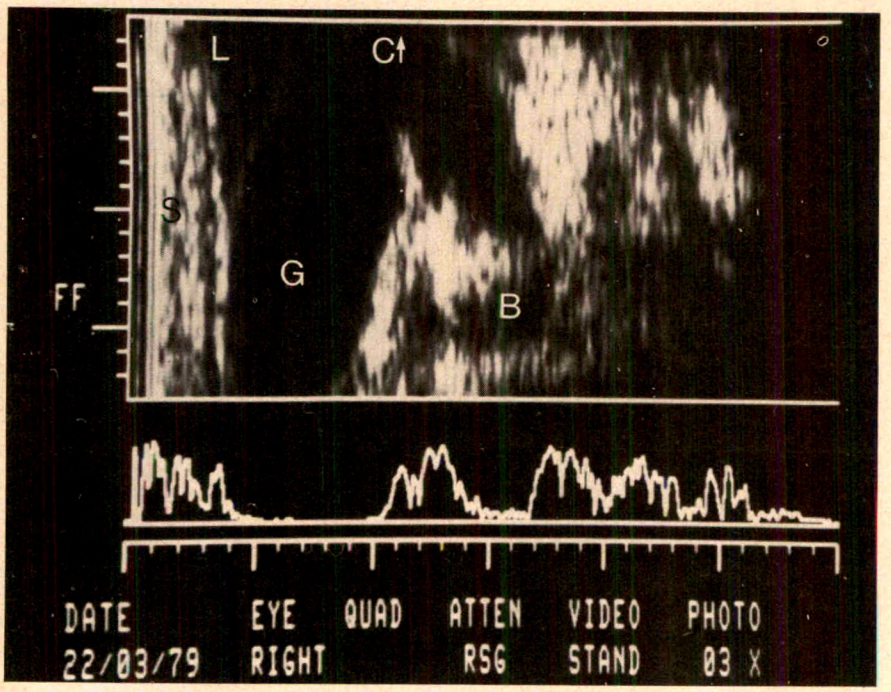

Fig 2.—Sagittal abdominal scan, 3 cm to right of midline demonstrates inferior margin of right lobe of liver (L), dilated gallbladder (G), and bowel (B): abdominal wall (S) and cephalad (C↑).

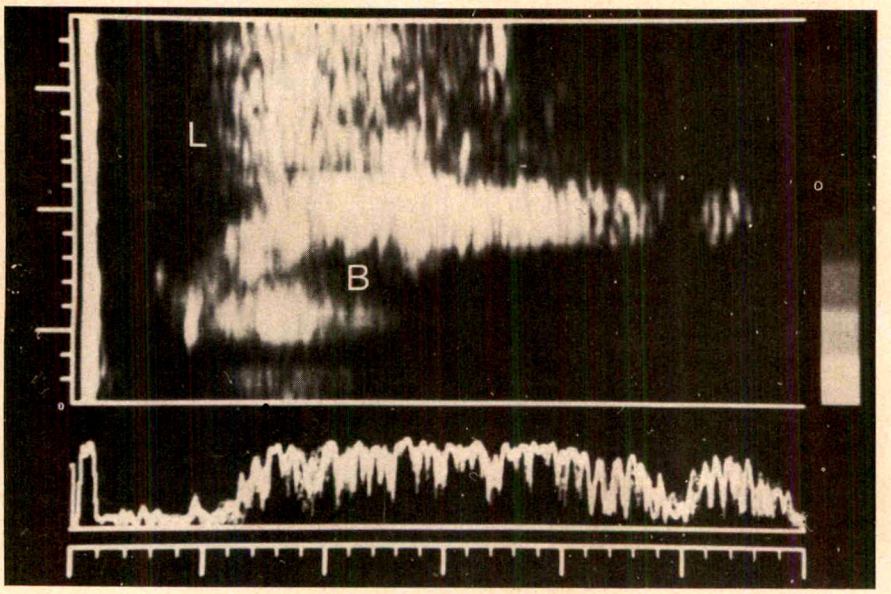
Fig 3.—Sagittal abdominal scan performed in same projection, four days later, showing only right lobe of liver (L) and bowel (B).



Our patient with group B streptococcal sepsis is of interest since the association of acute gallbladder dilation with scarlet fever is well documented.[3] The pathogenesis of the hydrops associated with group A streptococcal infection is not certain. Among cases undergoing surgical drainage, isolation of the organism from bile is uncommon.[3] Hyperplasia of the lymph nodes adjacent to the junction of the cystic and common bile duct has been described in some cases.[7,8] The possibility of transient edema of the biliary ducts related to streptococcal sepsis has also been suggested.[2,9] The hydrops in our patient was associated with generalized edema and abdominal distention.

Several reports of hydrops of the gallbladder in older children have recommended treatment with cholecystectomy or cholecystotomy.[1-3,9] Ultrasonography, as previously reported by Kumari et al[10] is a valuable noninvasive tool to diagnose hydrops. By sequential ultrasound studies, the resolution of the dilation can be monitored and surgical intervention avoided in a critically ill patient.

Apparent Protein-Losing Enteropathy Associated With Giardiasis

Giardia lamblia is a flagellated protozoan that frequently inhabits the human proximal small intestine and is pathogenic on occasion.[1,2] When it is pathogenic, mucosal injury may be minimal to severe, and frequently is patchy in distribution.[1-3] Diarrhea, steatorrhea, nausea, anorexia, and epigastric fullness have been well established, but association with a protein-losing enteropathy has not been appreciated.[1-4] We studied a 5-year-old boy with giardiasis and apparent protein-losing enteropathy that subsequently resolved after treatment of giardiasis with metronidazole.

Report of a Case.—A 5-year-old boy was admitted to the University of California Medical Center, San Francisco, with a two-day history of swelling in his legs and around his eyes, as well as abdominal protuberance. Six days prior to admission, the patient had begun to vomit, but there was no fever, diarrhea, or other symptoms. Medical history and results of a systems' review were unremarkable. One month prior to admission, the patient had visited a campground and drunk well water there. Results of physical examination were unremarkable except for mild periorbital, pretibial, and pedal edema without abdominal distention.

Results of laboratory studies included the following values: hemoglobin, 12.9 g/dL; hematocrit, 38%; and WBC count, 7,300/cu mm, with normal differential count and normal numbers of platelets and eosinophils. There were normal sedimentation rates, serum transaminase levels, creatinine levels, electrolyte levels, ammonia levels, folate levels, and vitamin B_{12} levels. Results of urinalysis and sweat tests were normal. Calcium level was 7.6 mg/dL; phosphorus level, 3.7 mg/dL; total protein level, 2.8 g/dL; albumin level, 2.2 g/dL; IgG level, 175 mg/dL (normal, > 500 mg/dL); IgM level, 77 mg/dL (normal, > 40 mg/dL); IgA level, 89 mg/dL (normal, > 55 mg/dL); IgE level, 31 units/mL (normal, < 100 units/mL); and prothrombin time, 13.5 s (control, 11.0 s). Stool examinations were negative for occult blood and reducing substances, and culture was negative for pathogens but did demonstrate *G lamblia* cysts. Quantitative stool fat collection (72 hours) was normal (< 7%). ^{51}Cr-labeled albumin was not available. Upper gastrointestinal-small bowel roentgenograms demonstrated mild thickening of the mucosal contour of the mid- and distal duodenum, as well as the jejunum. A small-intestinal biopsy specimen is shown in the Figure.

After apparent intolerance to quinacrine hydrochloride (Atabrine), treatment with metronidazole (Flagyl) for ten days resulted in a disappearance of the peripheral edema and normalization of all laboratory values; levels of serum protein rose to 6.3 g/dL, and of albumin to 4.1 g/dL. Repeated examinations for parasites were negative. The patient has continued to do well clinically at a follow-up examination three months later.

Comment.—As previously mentioned, *G lamblia* is a protozoan agent

Specimen of distal duodenum. Epithelium is columnar and intact. Villi are tall and leaf-like. Lymphocytes, plasma cells, and occasional eosinophils are present in lamina propria. Flagellated structures (arrowheads and inset) are present adjacent to and in apposition to epithelial surface (hematoxylin-eosin, ×125; inset, ×250).

that may infest the proximal small intestine, specifically the duodenum and jejunum. Mucosal damage may result.[1-5] The infestation occurs by ingestion of cysts of *G lamblia*, the source being feces of an infected person or water and food contaminated with contaminated feces.[1-5] The prevalence in the United States has been estimated as 7% to 8%.[1-5]

Clinically, most children are asymptomatic. Others may have an acute onset of nausea, diarrhea (watery), decreased appetite, with or without crampy abdominal pain, frequently self-limited in course.[1,2,6] Still others may have an intermittent or chronic course, characterized by diarrhea, sometimes steatorrhea, and variable failure to thrive.[1,2,5] Secondary disaccharide intolerance, particularly lactose, may be a prominent feature. There is a higher incidence of giardiasis in children with immunodeficiency states, eg, acquired hypogammaglobulinemia.[3,5] Protein-losing enteropathy has not been appreciated in giardiasis, especially without diarrhea, as in our patient. The possible mechanisms in our patient remain unknown, although mechanical blockade of the mucosa by the parasite, submicroscopic changes in the mucosa, as suggested by other investigators in explaining malabsorption in giardiasis, may play a role.[7,8] The resolution of these features coincided with successful treatment with metronidazole, since quinacrine had not been tolerated. Repeated examinations for parasites were negative, and clinical status and laboratory study results became normal. Thus, our patient represents an apparent protein-losing enteropathy associated with intestinal giardiasis.

Fatal Group G Streptococcal Sepsis in a Preterm Neonate

The etiology of neonatal infections has undergone certain changes, with an important consideration being the emergence of the group B streptococcus as a major pathogen in the newly born. A number of non-group B streptococci have been shown to cause infections clinically simulating group B streptococcal infection, namely, A, C,[1] D,[2] and more recently, G.[3-6] We report a fatal case of group G streptococcal septicemia in a 2-kg preterm infant.

Report of a Case.—Twin males were born to a 27-year-old, gravida 2, para 1, white woman by spontaneous vaginal delivery at 32 weeks' gestation. The pregnancy had been uncomplicated, and artificial rupture of membranes three hours prior to delivery yielded clear amniotic fluid. Each had Apgar scores of 5 and 6 at 1 and 5 minutes of age. Initial examination revealed the lengths and head circumference to be in the 50th percentile for the gestational age and the weights to be in the 50th and 75th percentiles, respectively. No congenital malformations were identified. Both infants experienced the early onset of respiratory distress. An umbilical arterial catheter was inserted in twin B and blood was obtained for culture. Both infants were intubated and ventilated because of the finding of increased partial pressure of carbon dioxide and were transferred to the regional neonatal intensive care unit at 3 hours of age.

Physical examination at this time revealed active, pink infants with good peripheral pulses and perfusion. The lung fields were clear on auscultation. A Gram-stained sample of the gastric aspirate from twin B revealed fewer than 5 polymorphonuclear leukocytes per high-power field and no organisms. The WBC count was 11,700/cu mm, with 46% polymorphonuclear leukocytes, 2% band forms, 37% lymphocytes, and 15% monocytes. A chest roentgenogram was consistent with the presence of hyaline membrane disease. By 14 hours of age, twin B had been weaned to a continuous positive airways pressure of 4 mm Hg and oxygen concentration of 27%, but at 20 hours of age, progressive hypoxemia and acidosis developed, which could not be reversed by sustained ventilatory assistance and infusions of sodium bicarbonate and tromethamine (Tham). Samples of blood and spinal fluid were obtained for culture. The Gram-stained specimen of the tracheal aspirate showed rare polymorphonuclear leukocytes, 0 to 3 squamous epithelial cells per high-power oil immersion field, and large numbers of Gram-positive cocci in chains. The blood showed marked neutropenia (total WBC count, 3,500/cu mm, with 8% polymorphonuclear leukocytes). A chest roentgenogram suggested bilateral pulmonary infiltrates. Antibiotics (penicillin G sodium and gentamicin sulfate) were given in appropriate doses. Clinical deterioration continued, with progressive hypoxemia, acidosis, hypotension, renal failure, hyperkalemia, and cardiac arrhythmias, and death occurred at 44 hours of age.

Autopsy performed on twin B demonstrated pneumonic consolidation of both lung fields and the presence of bilateral intraventricular hemorrhages. Microscopic examination of the lung showed diffuse intra-alveolar fibrin deposition, with scattered RBCs, polymorphonuclear leukocytes, and macrophages. Eosinophilic hyaline membranes were seen throughout. On microscopic examination, the brain showed hemorrhagic congestion of the choroid with packed RBCs and fibrin in the ventricles.

Twin A showed improvement with ventilatory support and was extubated at 30 hours of age and placed in 30% oxygen. In view of twin B's deteriorated condition from presumed sepsis, samples were obtained from twin A for culture and the infant was treated with penicillin for ten days.

Cultures of gastric and tracheal aspirates, nose, axilla, CSF, and blood from twin B were studied. Blood cultures were processed radiometrically by the use of Bactec (Johnson Laboratories, Cockey's Ville, Md). Three sets of blood were drawn for aerobic and anaerobic culture study, two sets on two successive days (at 2 and 30 hours of age) and one set post mortem. The blood sample taken at 30 hours of age was positive, after 24 hours incubation, for a β-hemolytic streptococcus. This organism was presumptively identified as Lancefield group G by the coagglutination method of Kronvall[7] and confirmed by the Laboratory Division of the Connecticut State Department of Health, Hartford, using Lancefield's precipitin method. The sample of tracheal aspirate obtained at 28 hours of age also yielded group G streptococcus. Cultures from the axilla, nose, and gastric aspirate, as well as the first and third set of blood cultures and culture of the CSF, were sterile. Similar cultures from the other

twin were uniformly negative.

Bacteriologic survey of the transport van, intensive care unit, and the incubator failed to disclose the presence of group G streptococcus. The mother of the twins remained asymptomatic at another hospital; vaginal culture was not performed.

Comment.—With the development of group B β-hemolytic streptococcus as a major pathogen in the neonatal period, other streptococci of Lancefield's classification have come under scrutiny. Group A, group C,[1] group D,[2] and group G[3-6] streptococci have been reported as probable causes of neonatal infections.

Group G streptococcal infections in humans have been reported since the late 1930s.[8] Group G streptococci have been isolated from a variety of human sources, including suppurative wounds, blood, urine, vaginal secretions, CSF, feces, and other body fluids.[9] The most frequently reported sources have been wounds,[9] the respiratory tract,[10,11] and the genital tract.[2,12]

Christensen et al[13] examined the frequency of isolation of β-hemolytic streptococci from urethral and cervical swabs in 364 female patients who were being studied for gonococcal infection and found the frequency of urogenital colonization by group G streptococcus to be 0.5%. In only rare instances, however, has neonatal sepsis been reported. Baker[3] and Ancona et al[6] cited instances in which group G streptococci were isolated from both the blood of the infant and the vagina of the mother; the mothers had prolonged rupture of membranes. There was a striking clinical similarity to "early onset" group B streptococcal infection, as noted in the present report. Brans[4] reported septicemia in two neonates. These cases differ in that in both instances, group B streptococci were isolated concomitantly with group G streptococci, although not necessarily from the same site. The author did not specify the methods used to differentiate the streptococci, but it is known that serologic cross reactions do exist between group B and group G streptococci.[14] Thus, one must question, on the basis of these dual isolates, the presence of group G streptococcus, and if so, its role in the disease process.

In our case, group B streptococci were not isolated from either twin. The streptococci were identified serologically by coagglutination with specific antisera. On 10% sheep blood agar plates, the colonies produced β-hemolysis but were tiny (< 1 mm in diameter). Colony morphology is variable and hence cannot be easily differentiated from colonies of group B streptococci that are larger (> 2 mm), gray, and often mucoid.

Nieburg[5] reported group G streptococcal sepsis in a full-term infant following an uncomplicated pregnancy, labor, and delivery. The clinical course was similar to that of our infant (absence of risk factors, progressive respiratory deterioration, shock, and coagulopathy) and ended fatally. Two out of three antemortem blood cultures yielded group G streptococcus. The fetal scalp electrode used in intrapartum fetal monitoring was implicated as effecting a possible port of entry for the organism. The fact that in our case, invasive procedures such as intubation and umbilical vessel catheterization were performed during transfer to the regional center, with subsequent positive cultures, raises the issue of nosocomial infection. Examination of our transport and nursery incubators and equipment revealed no evidence of contamination. Hence, it is likely that under the circumstances described, the infant was infected during parturition.

Reports of neonatal infections caused by streptococci of different serologic groups underscore the need for the precise identification of streptococcal isolates through the use of group specific antisera.

TAR Syndrome: Dorsal Pedal Edema and Excessive Perspiration

The thrombocytopenia absent radius (TAR) syndrome is inherited in an autosomal-recessive manner and consists of thrombocytopenia during the neonatal period, a leukemoid reaction during the first year of life, eosinophilia, anemia, bilateral absence of the radius, radial deviation of the hand, abnormalities of the ulna and humerus, other skeletal anomalies, micrognathia, and congenital heart disease. Bleeding, specifically intracranial bleeding, is potentially the most serious problem.

Report of Cases.—We recently evaluated this syndrome in eight patients and noted two findings that have not been, to our knowledge, previously reported in association with this syndrome: dorsal edema of the feet and excessive perspiration. Two of the patients were brothers and two were first cousins. Six of the eight patients had nonpitting edema of the dorsa of their feet at birth. The duration of the edema varied. In one infant, it was no longer present at 3 months and in another it had disappeared by 18 months. It continues to be present in a 1-month-old, a 5-month-old, and two 15-month-old children. The cause of the edema is not known, although it may represent an abnormality of the lymphatic system. Some of the patients also had redundancy of the skin of the neck.

Excessive perspiration occurred in seven of the eight patients and is still present in all of the patients, the oldest being 21 months. This may be secondary to vasomotor instability or an increased metabolic rate.

Comment.—We have noted that some patients with missing limbs also have increased perspiration that may be related to decreased body surface. We conclude that dorsal edema of the feet and excessive perspiration are frequent findings of the TAR syndrome.

Tracheoesophageal Fistula in Parent and Offspring: A Rare Occurrence

Infants born with esophageal atresia and tracheoesophageal fistula (TEF) had a grim prognosis prior to the 1940s. However, with better anesthesia, better operative management (delayed, staged, or primary), and neonatal intensive care units, the survival of patients with this anomaly has increased to 75% to 90%. The patients who survived in the 1940s and 1950s are now producing children who may have an increased likelihood of esophageal anomalies.

This report details the occurrence of esophageal atresia with a distal fistula in the father and an H-type tracheoesophageal fistula in his daughter.

Report of Cases.—CASE 1.—A 2.9-kg baby boy born at term in 1955 vomited all feedings and had heavy oral secretions noted after a normal delivery at an outlying hospital. Diagnosis of esophageal atresia was made on the fourth day of life and a gastrostomy was performed with the patient under local anesthesia. The infant was fed through the gastrostomy for seven days. (This is not desirable because of the risk of pulmonary aspiration through the tracheoesophageal fistula. Division of the fistula and gastrostomy or intravenous hyperalimentation is preferable, if the condition of the infant precludes immediate repair of the esophageal atresia). At 12 days of age, the infant was transferred to Children's Hospital of Pittsburgh. A transpleural division of the tracheoesophageal fistula and a primary esophageal anastomosis was performed. The child did well and was discharged on the 13th postoperative day. Twenty-two years later, his daughter was admitted to Children's Hospital of Pittsburgh with recurrent pneumonia.

CASE 2.—A 6-month-old girl had been hospitalized elsewhere for pneumonia at 3 and 5 months of age. The referral to Children's Hospital of Pittsburgh was made for "problems with swallowing liquids" and "aspiration pneumonia." As an infant, she would refuse liquids in favor of solid baby foods or formula thickened with cereal. The parents noted coughing and choking when liquids were taken. The diagnosis of an H-type TEF was established by barium swallow. At endoscopy, the fistula was easily visualized at the level of the sixth cervical vertebra. The child weighed 4.1 kg and seemed healthy, except for occasional cough when liquids were swallowed. At operation, a ureteral catheter was passed endoscopically from the trachea into the esophagus. The fistula was approached through a right cervical incision. Identification and division of the fistula was easily accomplished, and the child went home in eight days, eating liquids and solids without any symptoms. She has been seen in follow-up examinations for more than a year and is perfectly well. She has a normal esophagram.

Comment.—Esophageal atresia occurs approximately once in every 4,000 live births.[1] The error in development is thought to occur during the third or fourth week of fetal life.[2] While the empirical chance of a single malformation recurring in immediate relatives is said to be 3% to 5%, this does not seem to be true in TEF. The occurrence of other anomalies (particularly the Vater association[3]) with TEF suggests a teratogen or genetic makeup that may influence several systems; the cardiovascular[4] and gastrointestinal systems[5] are most often involved.

We are aware of two reports of tracheoesophageal fistula in mother and child.[6,7] The malformation has occurred in identical twins,[8,9] but many identical twins have been born with only one of the twins having the anomaly.[10] Brothers, sisters, cousins, and brother-sister combinations with TEF have been described.[11] Further study of children born to parents who had TEF may give additional insight into the influence of heredity as an etiologic factor.[12]

We conducted an informal mail survey of the chiefs of service of 14 major pediatric surgical centers in North America that treat a total of 125 to 150 patients with TEF per year. No cases of TEF in parent and child could be remembered as having occurred in these institutions over a ten- to 25-year period, although no formal review of clinical records was carried out.

When a family history of TEF exists, the pediatrician should be quick to rule out an esophageal atresia by the passage of a nasogastric tube under fluoroscopic control; this is almost always diagnostic by showing it curling in the blind pouch. A barium swallow and/or endoscopy is needed for the diagnosis of an H-type fistula.

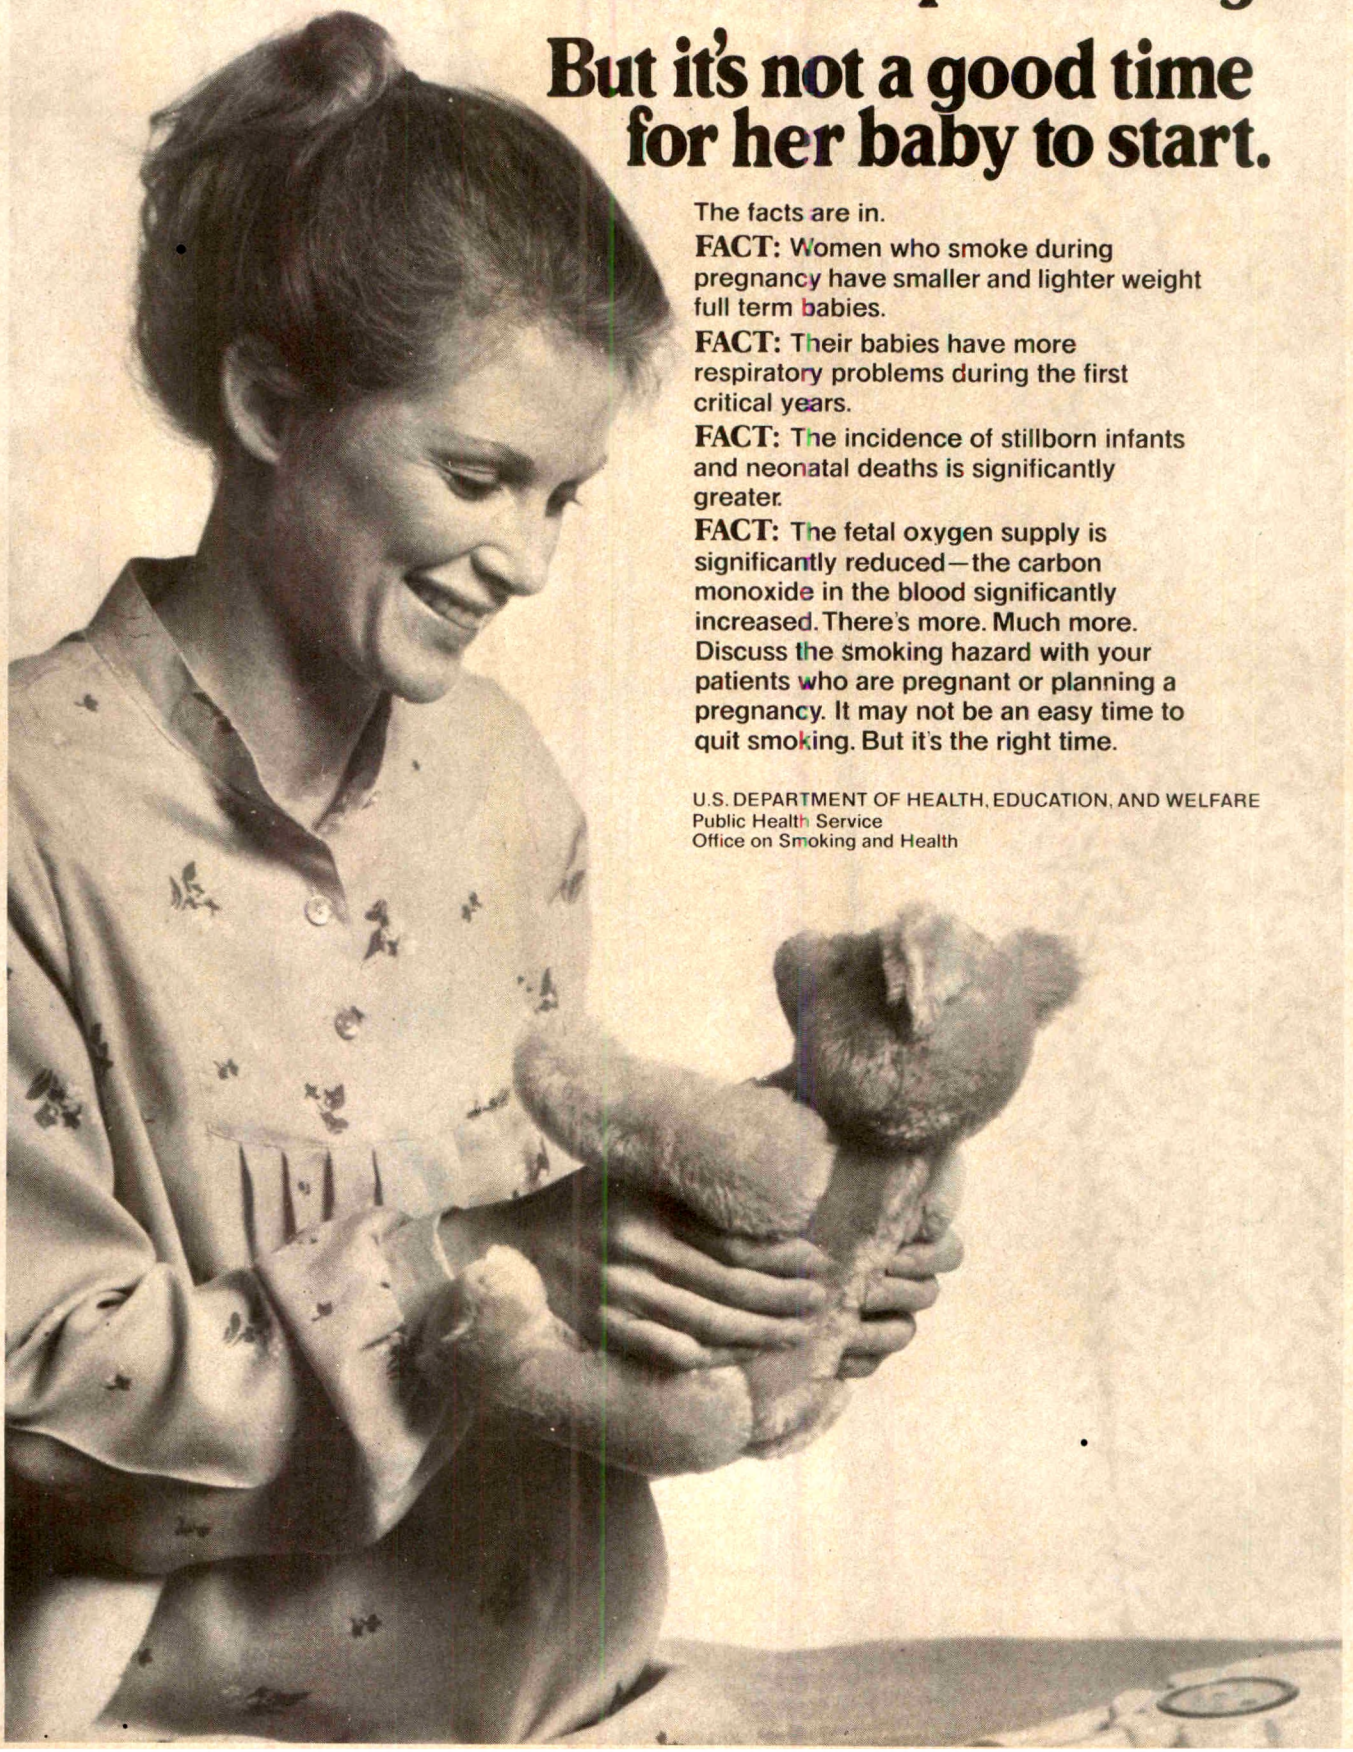
This is not an easy time for her to stop smoking.

But it's not a good time for her baby to start.



The facts are in.

FACT: Women who smoke during pregnancy have smaller and lighter weight full term babies.

FACT: Their babies have more respiratory problems during the first critical years.

FACT: The incidence of stillborn infants and neonatal deaths is significantly greater.

FACT: The fetal oxygen supply is significantly reduced—the carbon monoxide in the blood significantly increased. There's more. Much more. Discuss the smoking hazard with your patients who are pregnant or planning a pregnancy. It may not be an easy time to quit smoking. But it's the right time.

Public Health Service
Office on Smoking and Health

NOW PETER

Attention Deficit Disorders* under control...
His natural abilities are coming through

Now Peter's enjoying more things at play as well as in school. He works better with his teacher and classmates... likes doing things with his dad... gets more natural pleasure out of family and friends.

Now that his concentration is improved, his natural abilities are coming through. He's functioning better. Under a well-integrated program of treatment for Attention Deficit Disorders (ADD), hyperactivity and impulsiveness are markedly reduced.

Ritalin (methylphenidate) can be a vital part of his regimen. With adjunctive use of Ritalin, many ADD children are better able to control hyperkinetic behavior —act in a more natural and appropriate manner.

A 20-year record of proven efficacy

Over the years, Ritalin has become an established choice for pharmacotherapy of ADD. In a report by the

BEHAVES MORE NATURALLY.

National Council on Child Health,[1] Ritalin was described as among the most effective and best-documented agents for stimulant therapy in hyperkinetic children.

Reduces hyperactivity, impulsive behavior

Ritalin has a well-documented record of success in relieving the dominant symptoms of ADD. As it reduces distractibility, disorganized behavior and hyperactivity, improved school performance usually results,[2,3] as well as better peer interaction.[2]

Generally well tolerated

Although side effects may occur with Ritalin, they are generally not serious. During prolonged therapy, anorexia, weight loss, and insomnia are among the most frequently encountered adverse reactions. (See Adverse Reactions section of the prescribing information.) Even though most children require long-term treatment, there is little evidence of habituation.[1]

Therapy with Ritalin should be considered only after a medical diagnosis of ADD has been confirmed. Dosage can usually be interrupted during weekends and vacations. In some cases, these drug holidays reveal "stabilization" in the child's behavior without medication. They may permit a reduction in dosage and eventual discontinuation of drug therapy if warranted.

*Attention Deficit Disorders: new designation by the American Psychiatric Association; formerly called Minimal Brain Dysfunction (MBD) or Hyperkinetic Syndrome.

Ritalin . . . only when medication is indicated for Attention Deficit Disorders

(methylphenidate)
as adjunctive therapy for ADD

Ritalin® C II
(methylphenidate)
Only when medication is indicated

Ritalin® hydrochloride (methylphenidate hydrochloride USP) C II

TABLETS

INDICATIONS

Attention Deficit Disorders (previously known as Minimal Brain Dysfunction in Children). Other terms being used to describe the behavioral syndrome below include: Hyperkinetic Child Syndrome, Minimal Brain Damage, Minimal Cerebral Dysfunction, Minor Cerebral Dysfunction.

Ritalin is indicated as an integral part of a total treatment program which typically includes other remedial measures (psychological, educational, social) for a stabilizing effect in children with a behavioral syndrome characterized by the following group of developmentally inappropriate symptoms: moderate-to-severe distractibility, short attention span, hyperactivity, emotional lability, and impulsivity. The diagnosis of this syndrome should not be made with finality when these symptoms are only of comparatively recent origin. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of central nervous system dysfunction may or may not be warranted.

Special Diagnostic Considerations

Specific etiology of this syndrome is unknown, and there is no single diagnostic test. Adequate diagnosis requires the use not only of medical but of special psychological, educational, and social resources.

Characteristics commonly reported include: chronic history of short attention span; distractibility, emotional lability, impulsivity, and moderate-to-severe hyperactivity; minor neurological signs and abnormal EEG. Learning may or may not be impaired. The diagnosis must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with this syndrome. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis. Appropriate educational placement is essential and psychosocial intervention is generally necessary. When remedial measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms.

CONTRAINDICATIONS

Marked anxiety, tension, and agitation are contraindications to Ritalin, since the drug may aggravate these symptoms. Ritalin is contraindicated also in patients known to be hypersensitive to the drug and in patients with glaucoma.

WARNINGS

Ritalin should not be used in children under six years, since safety and efficacy in this age group have not been established.

Sufficient data on safety and efficacy of long-term use of Ritalin in children are not yet available. Although a causal relationship has not been established, suppression of growth (*ie*, weight gain, and/or height) has been reported with the long-term use of stimulants in children. Therefore, patients requiring long-term therapy should be carefully monitored.

Ritalin should not be used for severe depression of either exogenous or endogenous origin. Clinical experience suggests that in psychotic children, administration of Ritalin may exacerbate symptoms of behavior disturbance and thought disorder.

Ritalin should not be used for the prevention or treatment of normal fatigue states.

There is some clinical evidence that Ritalin may lower the convulsive threshold in patients with prior history of seizures, with prior EEG abnormalities in absence of seizures, and, very rarely, in absence of history of seizures and no prior EEG evidence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. In the presence of seizures, the drug should be discontinued.

Use cautiously in patients with hypertension. Blood pressure should be monitored at appropriate intervals in all patients taking Ritalin, especially those with hypertension.

Symptoms of visual disturbances have been encountered in rare cases. Difficulties with accommodation and blurring of vision have been reported.

Drug Interactions

Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors.

Human pharmacologic studies have shown that Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.

Usage in Pregnancy

Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence

Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism, because such patients may increase dosage on their own initiative.

Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS

Patients with an element of agitation may react adversely; discontinue therapy if necessary.

Periodic CBC, differential, and platelet counts are advised during prolonged therapy.

Drug treatment is not indicated in all cases of this behavioral syndrome and should be considered only in light of the complete history and evaluation of the child. The decision to prescribe Ritalin should depend on the physician's assessment of the chronicity and severity of the child's symptoms and their appropriateness for his/her age. Prescription should not depend solely on the presence of one or more of the behavioral characteristics.

When these symptoms are associated with acute stress reactions, treatment with Ritalin is usually not indicated.

Long-term effects of Ritalin in children have not been well established.

The Ritalin tablets (5 and 20 mg) contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

ADVERSE REACTIONS

Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathological findings of necrotizing vasculitis, and thrombocytopenic purpura); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmia; abdominal pain; weight loss during prolonged therapy. Toxic psychosis has been reported. Although a definite causal relationship has not been established, the following have been reported in patients taking this drug: leukopenia and/or anemia; a few instances of scalp hair loss.

In children, loss of appetite, abdominal pain, weight loss during prolonged therapy, insomnia, and tachycardia may occur more frequently; however, any of the other adverse reactions listed above may also occur.

DOSAGE AND ADMINISTRATION

Children (6 years and over)

Start with small doses (*eg*, 5 mg before breakfast and lunch) with gradual increments of 5 to 10 mg weekly. Daily dosage above 60 mg is not recommended. If improvement is not observed after appropriate dosage adjustment over a one-month period, the drug should be discontinued.

If paradoxical aggravation of symptoms or other adverse effects occur, reduce dosage, or, if necessary, discontinue the drug.

Where possible, drug administration should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued therapy. Improvement may be sustained when the drug is either temporarily or permanently discontinued.

Drug treatment should not and need not be indefinite and usually may be discontinued after puberty.

HOW SUPPLIED

Tablets, 20 mg (peach, scored); bottles of 100 and 1000.

Tablets, 10 mg (pale green, scored); bottles of 100, 500, 1000 and Accu-Pak® blister units of 100.

Tablets, 5 mg (pale yellow); bottles of 100, 500 and 1000.

Dispense in tight, light-resistant container (USP).

665382 C80-14 (1/80)

Consult complete product literature before prescribing.

Letter From Abroad

Great Expectations

London.—An obstetrician I have the good fortune to work with from time to time telephoned me with a curious and novel problem. A foreign lady, aged 31 years and expecting her first baby in about four weeks, had consulted him about her forthcoming confinement. Not having seen her previously, he quite properly arranged for her to have an ultrasound scan. Clinically, her condition was unremarkable, but the scan showed a large swelling on the anterior abdominal wall of the fetus, correctly interpreted as highly suggestive of an exomphalos, omphalocoele, or gastroschisis. The scan had been performed in a highly respected department by experts using the latest equipment. The question now was—or rather, the questions now were—what further investigations should be made, should she be delivered after an induction or by an elective section two or three weeks before term, and how much should he tell the parents?

Prenatal detection of fetal abnormality is a mixed blessing, and the problems raised by such unexpected findings late in an otherwise normal pregnancy are likely to be encountered more often with the development of high-resolution ultrasound imaging. Its usefulness in detecting neural defects, hydrocephaly, and microcephaly is already well established. Less clear is what to do about cystic kidneys or an enlarged liver. The discovery of an exomphalos was new to both of us.

The question of further tests was relatively easy to resolve. Both serum and amniotic fluid α-fetoprotein levels would probably be elevated, but even if the tests discriminated reliably between normal and abnormal babies at 36 weeks' gestation, knowing the levels did not seem to offer any immediate practical application. In days happily gone by, we used to show the fetal intestine by putting a contrast medium into the amniotic sac before doing an intrauterine transfusion for severe Rhesus haemolytic disease. The same technique would presumably demonstrate loops of bowel that have spilled out of a defect in the abdominal wall provided they are not obstructed and viable, but roentgenograms during pregnancy are not respectable any more and paediatric surgeons often overreact to the presence of contrast material in the bits they operate on, as do anaesthetists.

The discussion about the mode of delivery was prompted by the obstetrician's fear that he might rupture the sac—or rather, that the sac might rupture spontaneously during the birth. The risk would presumably be less with a smaller baby, and less still if the delivery were by an elective cesarean section one or two weeks before term, or earlier if she went into spontaneous premature labour. The question hinged on whether such sacs ruptured during labour and, like most paediatricians, my total experience of some half-a-dozen cases was not enough to go by. In the course of more than 20 years' practice, I have often been astounded by the immense swellings that have run the gauntlet of the human female birth canal and remained intact—myelocoeles, encephalocoeles, omphalocoeles, and even conjoint twins. I have also seen severe gastroschisis with herniated liver and spleen and masses of unhealthy purple intestine, but in which any sac had disappeared long before the delivery. I promised to put the question to our paediatric surgeon, but before I had the chance to do so the patient was admitted in early labour.

The good Boy Scouts' motto is to "Be Prepared." Caught distinctly unprepared by the unexpected onset of a few contractions, the wisest plan seemed to be to postpone labour while the hitherto leisurely process of decision making proceeded at a more pressing pace. The question of what to say to the parents depended on whether any intervention was planned. It was agreed that honesty was the best policy and that patients are entitled to be adequately informed about their state of health. On the other hand, ignorance can be bliss and silence golden. The lady was not English, and a condition such as a gastroschisis could take a lot of explaining. It was clearly unthinkable to subject her to a cesarean section without telling her why, but there was much to be said for keeping quiet about the results of the ultrasound scan if she was to go through a normal labour.

Her contractions ceased and she fortunately went out of labour as our paediatric surgeon confirmed that omphalocoeles rarely rupture during delivery and that those which had ruptured probably did so long before labour. Based on an analysis of his last 70 cases, his experience was reassuring. The discussion had the added benefit of forewarning him of a possible emergency repair now seemingly done with sterile dura specially imported from German crania and he hastened to the operating room to make sure he had an adequate supply in stock.

The following week, the membranes ruptured and she went into labour. As happens in all good fiction on these occasions, an obstetrician, an anaesthetist, and a paediatrician converged on the labour ward at 2 AM. The choice of physician over surgeon at the delivery had been dictated by several elementary considerations. It is not difficult to wrap up a bit of omentum on a temporary basis, but skillful resuscitation is not everybody's forte, and who but a physician would recognise whether the baby had a chromosomal disorder or other congenital abnormalities? A selection of clear, plastic, nonadherent sterile dressings had already been purloined from the operating room, there was a "silver swaddler" on the resuscitation trolley, and I had a roll of unsterile but microbially irreproachable "cling-film" sandwich-wrap in my car.

One of the pleasures of having to

attend a delivery at 2 AM in recent years is the tranquil atmosphere promoted by a good obstetrician and a good anaesthetist. Gone are the days of maternal distress, cries of anguish, and the shouting of people exhorting some poor woman to push or not push as the case may be. Epidural analgesia must surely be one of the greatest blessings bestowed on women of childbearing age by modern medicine and the curious fanaticism for "natural childbirth" by some is quite incomprehensible to me. Its one occasional drawback as far as I am concerned is that it has encouraged the presence of fathers at deliveries. A few agonising screams would soon drive them to the most distant part of the building, but now that mothers are wreathed in smiles under the blissful relief of an effective epidural, they jollificate in their sport coats, cameras in one hand and often a drink in the other, as if it were some kind of birthday party, which of course it is. I admit I am prejudiced, but the trouble with being a paediatrician is that we see the abnormalities—the sudden catastrophes for which most fathers seem to be totally unprepared.

This particular father was exceptional in that he looked anxious, apprehensive, subdued, and thoroughly ill at ease. If anything, he looked even more so when he realised that a paediatrician had been called in. He went and sat miserably by himself in a corner, but cheered up a little when I told him that I was merely there to make sure I should have no work to do. Normal babies cannot be had to order and abnormalities sometimes happen, but I said that it was an inexplicable fact that my services were usually superfluous when I was present and urgently needed when I was not. He seemed reassured by this unscientific explanation and said nothing more until it was all over, when he shook my hands effusively and could not thank me enough, as if it had all been my doing.

The baby, incidentally, a 2,912-g (6½-lb) girl, was perfectly normal—an eventuality that we had not considered. If there is a moral, and I am not saying there is, it is surely:

It is better to do nothing than to do something when nothing should be done.

HERBERT BARRIE, MD, FRCP

Drug Advertising

Sir.—I am concerned that two drugs that have been judged to lack effectiveness are being advertised in the JOURNAL. Actifed-C and Tuss-Ornade had been evaluated by proper committees of the National Academy of Sciences more than a decade ago and found ineffective for any indication. Yet they have been advertised in the JOURNAL month after month, influencing pediatricians and residents. The advertising copy of all carry the legend that "there is a lack of substantial evidence that this . . . drug has the effect purported."

What this means is that the AMA's official journal carries advertisements for drugs that are ineffective. Both drugs were also branded "irrational mixtures" by the AMA itself in 1971.

Whereas the drugs do not have efficacy, their side effects are real and can be serious. The risk-to-benefit ratio is unacceptably high—in brief, the drugs do no good, but may cause a lot of harm. Should the official journal of the AMA continue advertising these drugs? I think not.

PETER BARNA, MSc
Centinela Hospital Medical Center
555 E Hardy St
PO Box 720
Inglewood, CA 90307

In Reply.—Mr Barna is not correct in stating that Actifed-C and Tuss-Ornade were found by committees of the National Academy of Sciences to be ineffective for any indication. If this had been so, then these drugs would have been withdrawn from the market by the Food and Drug Administration (FDA). The judgment made was that the effectiveness of these drugs was not proved by clinical trials conducted by experts. The companies that market these drugs have been permitted by the FDA to continue to market them for a limited period of time or until their effectiveness has been proved by controlled clinical trials. The advertisements for these drugs carries the notice that there is lack of substantial evidence for the effect purported, but this does not prove that they are ineffective. The AMA Council on Drugs adopted a position in the early 1970s that "drug combinations are irrational." Such a sweeping condemnation appears to many physicians to be itself irrational.

Mr Barna states that the risk-to-benefit ratio for these drugs is unacceptably high, but offers no supporting data for such a judgment. Obviously, more experienced evaluators of drugs convened by the National Academy of Sciences and also those employed by the FDA disagree with Mr Barna, for these drugs were not removed from the market.

When all the evidence is in and the final judgment arrived at, the AMA will respect that judgment in acceptance of advertising.

Hyperuricemia in Cyanotic Congenital Heart Disease

Sir.—The report by Dearth et al (JOURNAL 132:900-902, 1978) called attention to the hyperuricemia that occurs with secondary polycythemia in patients with congenital cyanotic heart disease. Although the pathogenesis of the arthritis, nephropathy, and urolithiasis in primary gout appear to be related to the duration of exposure to hyperuricemia and degeee of elevation of serum urate concentration,[1] the same conclusion cannot necessarily be reached in those patients with hyperuricemia that results from polycythemia secondary to cyanotic heart disease.

In an earlier publication on the natural history of 57 patients with the

Eisenmenger syndrome,[2] hyperuricemia (7 mg/dL to 12 mg/dL; mean, 10.5 mg/dL) was present in all of those in whom serum uric acid determinations were made, namely seven patients in the original communication and 19 obtained subsequent to publication. Despite comparably high hematocrit and serum uric acid levels, of 41 patients either first seen as adults or followed from childhood into adult life (up to 18 years of age; average, 5 years), in only two men, aged 25 and 32 years, did acute gouty arthritis develop. Although this 5% incidence in a small sample is higher than that in the Framingham study,[1] in which the incidence was 0.2% at a mean age of 44 years and 1.5% at a mean age of 58 years, it still suggested to us that an heritable predisposition (polygenic?) to gout,[3] in addition to the polycythemia and resultant hyperuricemia, is required.

The overall incidence of urolithiasis in primary gout has been reported as 22% by Yü and Gutman[4] and as high as 40% in men at serum uric acid levels of 9 mg/dL or greater.[1] In secondary gout, the reported incidence is 42%.[4] None of our 57 patients, however, showed evidence of calculi over the period of observation.

Fifteen subjects were examined postmortem. Four were children between the ages of 9 and 14 years, five young adults aged 17 to 23 years, and six older adults ranging from 34 to 58 years. Similar to the report of Somerville,[5] none showed nephropathic change attributable to the hyperuricemia.

While admittedly the Mayo Clinic study was retrospective and offered no follow-up as to the eventual development of gouty arthritis, urolithiasis, or nephropathy in their patients, our data suggest that these manifestations are relatively uncommon sequelae. I question, therefore, the recommendation of a therapeutic trial of allopurinol to lower the serum uric acid level, inasmuch as the risk of these complications of hyperuricemia does not seem to be so "real," nor is the use of allopurinol in hyperuricemic states so "safe" as they postulate.

Side effects from the use of allopurinol may occur in about 20% of all patients.[6] Some may be extremely serious and occasionally fatal. Toxic manifestations reported have included gastrointestinal intolerance, alopecia, bone marrow suppression, hepatitis, vasculitis, and drug rashes. The latter are apparently more frequent and serious in patients receiving both allopurinol and ampicillin, an antibiotic commonly used in pediatric practice.

Childhood Brachial Plexus Neuropathy

Sir.—We enjoyed reading the recent paper by Charles and Jayam-Trouth regarding brachial plexus neuropathy (BPN) in childhood (JOURNAL 134:299-300, 1980). We also have had experience with this disorder and agree that an infectious cause seems likely, particularly in patients with CSF pleocytosis.

However, we disagree with the authors' conclusions that childhood BPN has a uniformly excellent prognosis. We recently reported on two children with BPN and one of them, a girl with onset at age 1 year, has had no functional improvement over a two-year follow-up period.[1] The child's left arm remains completely useless and extensive atrophy has occurred. We are also concerned about the authors' case 3, who has shown little improvement of limb weakness in the interim between the six-month and one-year examinations.

Childhood BPN seems to be an uncommon disorder, and despite occasional case reports in the literature the extent of our knowledge remains limited. Although the prognosis of adult BPN has been established with some certainty,[2] we must use caution in extrapolating these results to children. Until a study comparable to that published by Tsairis and co-workers[2] critically examines this entity in childhood, we should not consider the prognosis of childhood BPN to be excellent in all cases.

Reye's Syndrome and Pancreatitis

Sir.—The report by Ellis et al in the JOURNAL (133:1014-1016, 1979) describing the postmortem finding of acute pancreatitis in four of 18 children with Reye's syndrome led us to determine the frequency of acute pancreatitis in our patients with this syndrome. The records of 27 such patients hospitalized in Albany Medical Center Hospital, Albany, NY, during 1971 through 1979 were reviewed. Postmortem examination was performed in six of the 11 subjects. Acute diffuse interstitial pancreatitis was found in one subject, a boy. Serum amylase level determined during the acute illness in three patients who survived was within the normal range.

Although an association between Reye's syndrome and acute pancreatitis no doubt exists,[1,2] the reason for this association remains unclear. It is possible that in Reye's syndrome, as well as in other diseases with hepatic dysfunction, the acute liver failure is the cause for the pancreatitis.[3,4]

Books

Pregnancy Metabolism, Diabetes and the Fetus: Ciba Foundation Symposium No. 63 (New Series), 326 pp, $39.50, Amsterdam, Excerpta Medica, 1979.

This book is an excellent compendium on maternal and fetal metabolism, their interrelationships, and the resultant perturbations on this unit caused by diabetes. There are 13 chapters, all of which are followed by a discussion, written by 26 well-recognized authorities in this field. Initial sections focus on normal maternal metabolism, transplacental substrate fluxes, and normal fetal nutrition. These chapters provide a smooth transition to two highly culled topics among many possibilities, namely, the hormonal regulation and induction of hepatic and placental enzymes. Remaining sections cover altered fetal metabolism secondary to maternal diabetes and its eventuality, in particular, in perinatal morbidity and congenital malformations. Each chapter and its discussion are replete with information, and all are well referenced and well written—despite the confusing use of pregnancy as an adjective in the book's title. The ensuing interchange of ideas by the collaborators is delightful, provocative, seemingly unedited, and occasionally vitriolic. I enjoyed listening in on such a brisk flow of data and concepts as the authors explicated or debated an issue.

This symposium on maternal diabetes is not for the general clinician who is seeking a differential diagnosis, workup, information on the controversies surrounding different therapeutic interventions, or long-term prognosis. This is by no means a comprehensive text for the management of diabetic pregnancy but rather a reservoir of information, providing a conceptual framework with which to approach this abnormal metabolic state. Unfortunately, the index is incomplete and often inconsistent. For example, several enzymes discussed in the text are readily found in the index but, for no apparent reason, many are not (glucose-6-phosphate dehydrogenase, acetyl CoA carboxylase, etc). Other neonatal complications of maternal diabetes of interest to the pediatrician, and quite controversial in etiology, include polycythemia, hypocalcemia, and renal vein thrombosis, all of which are overlooked in this book. Moreover, a couple of chapters consist entirely of the author's research, presented as a journal article.

The above-mentioned concerns are far outweighed by the scientific scholarship and expertise of the contributors, making this book a necessity for those interested in normal maternal metabolism and the chronic somatic and biochemical adaptations by the fetus to maternal diabetes.

KENNETH MCCORMICK, MD

Rochester, NY 14642

Outlines of Muscular Dystrophy, by Yves M. Rideau, 160 pp, $17, Poitiers, France, Faculte De Medecine, 1978.

This monograph was written with the express purpose of disseminating simple, practical knowledge about muscular dystrophy. It was originally published in French and is distributed by the French Muscular Dystrophy Association.

The discussion is limited to three major genetic groups of muscular dystrophies: the sex-linked form represented by the severe Duchenne's and benign Becker's types, the autosomal recessive form represented by the limb-girdle type, and the autosomal-dominant form represented by the facioscapulohumeral type.

Well-presented illustrations and statistics cover most aspects of these forms of muscular dystrophy. They may be useful as background material in discussion with patients.

Unfortunately, the text is frequently redundant, poorly edited, and contains many typographical errors. The translation often contains gallicisms that make the book difficult to read at times.

The discussion of the literature lacks depth. This reduces the book's usefulness for more advanced professionals in the field of myopathies. A further limitation is the description of orthopaedic appliances that differ from those used in the United States.

The book may be a good primer for beginning medical students and health professionals, but has no direct value for experienced neurologists except for its excellent illustrations and useful statistics.

Care of the High Risk Neonate, ed 2, by Marshall H. Klaus and Avroy A. Fanaroff, 437 pp, $19.50, Philadelphia, WB Saunders Co, 1979.

A former Chief Editor observed in this JOURNAL that "when, from time to time, a comprehensive treatise is written covering a field where such a treatise was needed, a welcome note is always sounded when a second or subsequent edition erupts." It seems only a few years ago that there existed no more than a few books relating to the management of newborn infants. Within the past decade, numerous treatises have been developed to meet this need, some with greater success than others. Among the most successful and the most widely used has been the first edition of the present book, and, not surprisingly, the second edition is bigger and better than the first. This edition has 20% more pages; extensive revisions have been included; a new chapter on antenatal and intrapartum care has been added; and the number of contributors, editors, and commentators has been doubled.

It is customary in describing multiauthored textbooks to comment on the uneven quality of the chapters written by different authors. The consistency in content and format from chapter to chapter throughout this book could only be the result of strong guidance and supervision by the editors. The editors had a clearly defined purpose in preparing a book that provided "a sound physiologic basis for current

perinatal practice," and they have succeeded in achieving this goal. An approach to the care of high-risk neonates and their families is presented, not in cookbook fashion, but by presenting and building on existing biochemical, physiologic, and behavioral information.

A critical synthesis of science and practical wisdom is presented, including such examples as, "the temperature of the delivery room is frequently set for the comfort of the medical staff rather than that of the newborn;" regarding infant feeding, "beware of any new preparation;" and when talking to the father of a recently transferred infant, "a cup of coffee and a quiet chat are most useful." Though the emphasis is on the high-risk infant, the needs of the normal newborn infant are not ignored. The appropriate use of charts, tables, illustrations, and pertinent references makes this a useful handbook for anyone involved in the care of newborn infants. Numerous procedures, including such practical concerns as the securing of orotracheal tubes, the insertion of umbilical-vessel catheters, and the progression of feedings in very low-birth-weight infants (< 1,250 g) are presented in detail.

A textbook by its very nature requires that existing information be presented from a specific and, oftentimes, dogmatic point of view. As a method of presenting conclusive points of view and at the same time indicating the uncertainties of these positions, the editors have invited outside experts in pediatrics and obstetrics to comment on the text and to present their opinions, which sometimes agree but often conflict with those of the authors. It is in part because of this public debate in conversational style that this book is frequently referred to as being "fun", a term that can be applied to few medical textbooks.

As can be expected with any summary of clinical management, this book includes approaches to some problems that will not satisfy every reader. But the differences of opinion are less important than the overall perspective of newborn care provided in this manual. This book describes in a lucid manner the care of high-risk newborn infants, based on the information available at this time. It is an informative and useful manual for medical students, pediatric residents, nurses, and pediatricians, including neonatologists. It is deserving of a position on the list of pediatric best sellers.

History of American Pediatrics, by Thomas E. Cone, Jr, 278 pp, 68 illus, $18.95, Boston, Little Brown & Co, 1979.

This volume represents a milestone in the study of child health and welfare in the United States. Its appearance is appropriate, as Samuel Radbill notes in the foreword, at the end of the International Year of the Child and in time for the golden anniversary of the American Academy of Pediatrics. The book does not fail this auspicious setting: it is attractive, well researched, lucidly written, and adequately illustrated. The publisher has added an attractive format, beautiful and easily read type, and faithful reproduction of photographs, which should please a wide audience.

The study is divided into three periods: colonial, with chapters on pastor- and governor-physicians, children discovered, and feeding colonial infants; the 19th century, with chapters entitled "Perplexing Obscurity and Embarrassing Uncertainty," "Explorers in an Almost Unknown Country," and "Infant Feeding of Paramount Concern"; and the 20th century, with chapters "Pediatrics Comes of Age," "Antibiotics and Electrolytes," "The Changing Face of Pediatrics," and "From Complexity to Simplicity." Each chapter concludes with representative but not exhaustive references, and the entire volume is indexed by name and subject. Lists of pediatric textbooks or other new publications are included; in the first two sections the historian speaks through the current observers by skillfully weaving their writings into the text.

Years ago, I had a long, continued debate with James A. Ford, then anthropologist at the American Museum of Natural History, New York. The subject was whether human culture swept along on its own initiative, producing leaders by inherent momentum, or whether leaders in thought and action altered culture and produced history. Cone follows the humanistic viewpoint and offers his present history largely through its leaders, not through the story of movements and organizations. The majority of the illustrations are photographs of leading men (plus two women, Josephine Baker and Virginia Apgar, which seems to slight women like Grace Abbott, Julia Lathrop, Katherine Bain, Edith Lincoln, Helen Taussig, and Mary Ellen Avery).

The story of colonial pediatrics is a litany of childhood illness and death, monotonous for three centuries because of medical ignorance and social neglect. The chief breaks in the litany are the interesting accounts of the pastor-physicians and governor-physicians, the progressive delineation of infectious diseases, and the significant story of smallpox inoculation by Boylston at the instigation of Cotton Mather. Some apology is due to our neighbors: the book's title preempts "American pediatrics" for the United States, to the exclusion of Canada and the Latin American countries, many of which had cities, universities, hospitals, and medical schools long before this country did. Moreover, Cone looks at colonial United States through English eyes and from the Atlantic Coast, forgetting the French settling of the St Lawrence, the Great Lakes area, and the Mississippi valley to Louisiana and Mobile, and the Spanish colonial empire in Florida, Texas, and the Southwest, with settlements like St Augustine and Santa Fe that antedated the English period.

Reflecting the bias of the earlier historians toward other races, little is said about the devastating effect of slavery on the health and welfare of black children, or the crushingly horrible result of European diseases on the totally susceptible American Indian. The latter can be inferred from notations in historical accounts, from the archaeological record of the past 50 years, from recent accounts of Carlton Gajdusek (who described the ravages of chickenpox among the Indians coming out of Paraguay's Gran Chaco), and the recent decimation of the Yanomamo by measles. Almost total obliteration of peoples and cultures may have occurred. Elvas, a chronicler of the DeSoto expedition, records that in 1540, on arrival of the army at Cofitachequi on the Savannah River, "Within a league and half about this towne, were great towns dispeopled and overgrown with grasse....The Indians said that two years ago there was a plague in that countrie...." Westward, DeSoto encountered many populous towns, but when the French

reached the lower Mississippi valley during the next century, scant traces of these populations remained, a finding confirmed by archaeologists. John Smith stated, "God had laid this Country open for us, and slain the most part of the inhabitants by civill warres and a mortal disease, for where I had seene one hundred or two hundred Salvages, there is scant ten to be found...." Du Pratz noted that the nations of Louisiana were once both numerous and populous, but were then "thinned and diminished" by distempers that included smallpox and a cold (influenza?).

The 19th century is marked during its early part by continued ignorance and high mortality (including terrible diarrheas) as the cities grew larger and less sanitary, by new epidemics (yellow and typhoid fevers, cholera, and malaria), but also by the advent of a few physicians interested in children. There were DeWees (still famous in the early years of my practice for DeWees carminative), the Meigs, and Benjamin Waterhouse, who introduced Jenner's cowpox vaccine to the United States. The latter half of the century saw pediatrics emerge as a specialty, beginning with Abraham Jacobi and Job Smith; Rotch and Emmett Holt followed. Holt's classic *The Care and Feeding of Children* and his textbook were standard during my medical school years at Tulane and in my early practice.

The 20th century opened with biochemistry. The eccentricities of percentage formulas were pediatric foibles by the time of my residency in 1930, replaced by the pragmatism of Marriott and Brennemann, and made redundant by the miracles of sanitation, refrigeration, and the expertise of dairymen and milk processors—too often unsung. Dr Cone might have shifted some of the emphasis from formulas to nutritionists, with the discovery and synthesis of vitamins (one of his rare errors is the statement that, in 1926, Goldberger and colleagues reported the discovery of riboflavin and identified it as the antipellagra factor).

I saw pellagra, rickets, beriberi, scurvy, hypoproteinemia, and hypoprothrombinemia in Louisiana during the 1920s and 1930s, among low-income families on restricted diets of canned foods and refined cereals. They had departed from the rich and varied supplements of native foods—fruits, berries, greens, nuts, wild game, and fish—of the forests, lakes, and fertile valleys of the Gulf coastal plain and the great rivers, which had abundantly sustained Indians, then whites and blacks, for untold centuries.

The other pediatric marvels are all in this volume: antitoxins, vaccines, and antibiotics; steroids and antimetabolites, endocrinology and hematology, transfusions and infusions, rehydration, and acid-base balance; newborns, prematures, and prenatal diagnosis; surgery and anesthesiology; the conquest of disease after disease; old nightmares and new. The pediatric giants are there to see, and all deserving. One should also view the collection of lesser lights, in offices and clinics, in hospitals, medical schools, and research laboratories, the nurses and technicians, the specialists in other fields, the organizations and foundations, the related industries, the governmental agencies, and the myriads of others who have joined to make the care of its children—not just in the great centers but from coast to coast—one of the crowning joys of our culture.

Cone is correct in saying that a person cannot justly assay pediatric history when he lives in the midst of it, but he can and does glory in it. He joins the other veterans who believe that we have lived through the golden age of pediatrics. He can also join us in apprehension over the new social pathology: family disintegration, child and drug abuse, teenage pregnancy, abortions, and litigation. We can only hope, for the children and those who care for them, that the right answers can be found again.

CLARENCE H. WEBB, MD
3904 Creswell Rd
Shreveport, LA 71106

The Children of Santa Maria Cauqué: A Prospective Field Study of Health and Growth, by Leonardo J. Mata, 395 pp, $19.95, Cambridge, Mass, MIT Press, 1978.

Students of geographic medicine, nutrition, and human development will find this volume an important addition to their libraries. Dr Mata reports on the extensive and intensive longitudinal study of nutrition and development conducted from 1963 to 1972 in an Indian village in Guatemala. This book details the health of 200 families and especially their developing children over an eight-year period with regard to the microbiologic, nutritional, environmental, and developmental components of general health status. Using multivariate analysis models, the author offers a comprehensive interpretation of the roles of nutrition and infection during pregnancy and early childhood within the natural setting that typifies a majority of the third world.

The health care practices for the newborn and infant provide interesting reading for the perinatologist, and the data provided relating to anthropometry of the newborn, immunoglobulin status, rates of congenital infection, and postnatal growth and health status are exhaustive. Unlike infants in developed countries, third-world infants suffer the combined effects of deficient diets and infection that resulted in a mortality of 576 per 1,000 live births, compared with a mortality of 199 per 1,000 live births in the United States for infants weighing 1,501 to 2,000 g at birth (1972 data); this further strengthens the argument that postneonatal and infant mortalities are strongly related to antenatal influences on fetal growth. Furthermore, the adverse effects of the environment, infection, and undernutrition claim disproportionate tolls, especially in infants of low birth weight.

The biologic and medical data presented in this book are extensive, and the analysis of infant physical growth and maternal and infant nutrition compare favorably with other published studies. The medical anthropologic analysis and public health perspectives offered in the 395 pages would well serve readers whose interests lie in public health, developmental pediatrics, and nutrition.

Increased Intracranial Pressure in Children, by William E. Bell and William F. McCormick, 485 pp, Philadelphia, WB Saunders Co, 1978.

This monograph is the second edition of a book that was first published in 1972 and is volume 8 in the excellent series, *Major Problems in Clinical Pediatrics*. The major new development of the intervening years was the computerized tomographic (CT) scan; a number of illustrations involving this technique have been added, as

well as a specific section of text. However, the majority of neuroradiologic illustrations continue to be photographs of air studies, which is defensible in that a single picture tells a much better story than a series of blurry CT cuts. I suspect that the third edition will contain CT illustrations of much better resolution, and more of the gross neuropathology will be presented in brain slices that conform to the standard CT image. On the subject of illustrations, it can be said that the monograph is profusely illustrated with excellent quality pictures of patients, pathology, and radiology.

The monograph has been updated and expanded in other areas as well, amounting to a doubling of the pages. For example, whereas Reye's syndrome was handled in one paragraph in the first edition, now it is discussed in more appropriate detail to bring into better perspective what probably amounts to the most common reason for acutely developing brain edema. Reye's syndrome has certainly replaced lead encephalopathy as a prototype cerebral edema problem of childhood. In fact, lead encephalopathy hardly deserves the chapter given to it because of its rarity in current practice. This is an interesting general commentary on medical progress, in this case due to screening programs in many cities for children at risk for lead ingestion. In the same context, if the authors were given an opportunity to reconsider their presentation of herpes simplex encephalitis today, they might give it more than one sentence because of the potential therapeutic effect of vidarabine treatment.

In summary, this is an excellent, well-presented monograph on an important subject and can be recommended as a most useful reference.

CHARLES F. BARLOW, MD
Boston Children's Hospital
300 Longwood Ave
Boston, MA 02115

Liver Disorders in Childhood, by Alex F. Mowat, 407 pp, Woburn, Mass, Butterworth Inc, 1979.

This is one of the first texts entirely devoted to pediatric liver disease. Written by Dr Mowat, a pediatrician and pediatric gastroenterologist, it combines a vast clinical experience with a format that is organized to assist the clinician approaching the child who has liver disease. The first few chapters deal exceedingly well with the normal liver of childhood from the standpoints of anatomy, physiology, and assessment of liver size. Though not exhaustive with regard to pathophysiology, the chapters are well referenced and quite up to date. The sections dealing with conjugated hyperbilirubinemia are complete with good tables to assist the physician in differential diagnosis. A discussion of the infectious and metabolic causes of liver disease together with the treatment of cirrhosis and portal hypertension relates to the pediatric experience and, thus, clearly fills a gap in current textbooks devoted to liver disease. The section on diagnostic modalities, particularly the use of newer radio imaging agents and ultrasonography, is short on providing examples and will undoubtedly be expanded in future editions.

In short, this is an excellent, well-written text of general interest to the pediatrician and the gastroenterologist that should serve as a good beginning for students and house staff. The selected current references provide good depth for those interested in further delineation of a particular point. This is an excellent monograph and well worth inclusion in the library.

60 YEARS AGO IN THE AJDC

Bodily Mechanics: Its Relation to Cyclic Vomiting and Other Obscure Intestinal Conditions

Mobilization of an army to fight as an expeditionary force in Europe had resulted in the examination of 2,570,000 men. Of these, 29.1 per cent. were rejected on physical grounds prior to drafting with one third more rejected after acceptance. The authors contend that much of this lack of fitness would be prevented by greater attention to bodily mechanics in childhood. A study of freshmen entering Harvard University revealed that 80 per cent. of a group of 700 students used their bodies in bad mechanical lines.

Fifteen cases of bad body posture in childhood are reviewed in this study. In each case, physical symptoms attributable to a relaxed posture were improved by exercises, adequate rest, and a body brace. The children ranged in age from 13 months to 10 years and were predominantly males. Symptoms of indigestion, poor appetite, nausea, gassiness, constipation, cyclic vomiting, acidosis, fatigue, and lifelessness were common. In some there was periodic abdominal pain, fever, headache, excessive perspiration, and attacks of diarrhea. Examinations showed poor posture with drooping shoulders, a flared lower rib cage, poor muscle tone, and protuberance of the lower part of the abdomen. Tenderness, suggestive of chronic appendicitis, was sometimes observed and one child was operated upon for acute intestinal obstruction. Roentgen-ray examinations demonstrated gaseous distention of the stomach, dilatation of the small bowel, sagging of the transverse colon, and colonic redundancy.

Treatment in these cases consisted usually of exercises and a routine of rest taken in special positions to correct the faulty mechanics. A body brace with an anteroposterior pad was fitted to the abdomen and back. In several a spring back brace was used. In some, periodic cleansing enemas were administered. Response to the treatment was variable. Some improved quickly, others not for months, or gradually over several years. The authors concluded that this was probably the cause of many if not most cases of recurrent vomiting. They stated that when the faulty mechanics have been corrected, the patients have shown a more speedy recovery than is seen in cases without the correction.—Fritz B. Talbot, Lloyd T. Brown, Boston (20:168-187, September 1920).

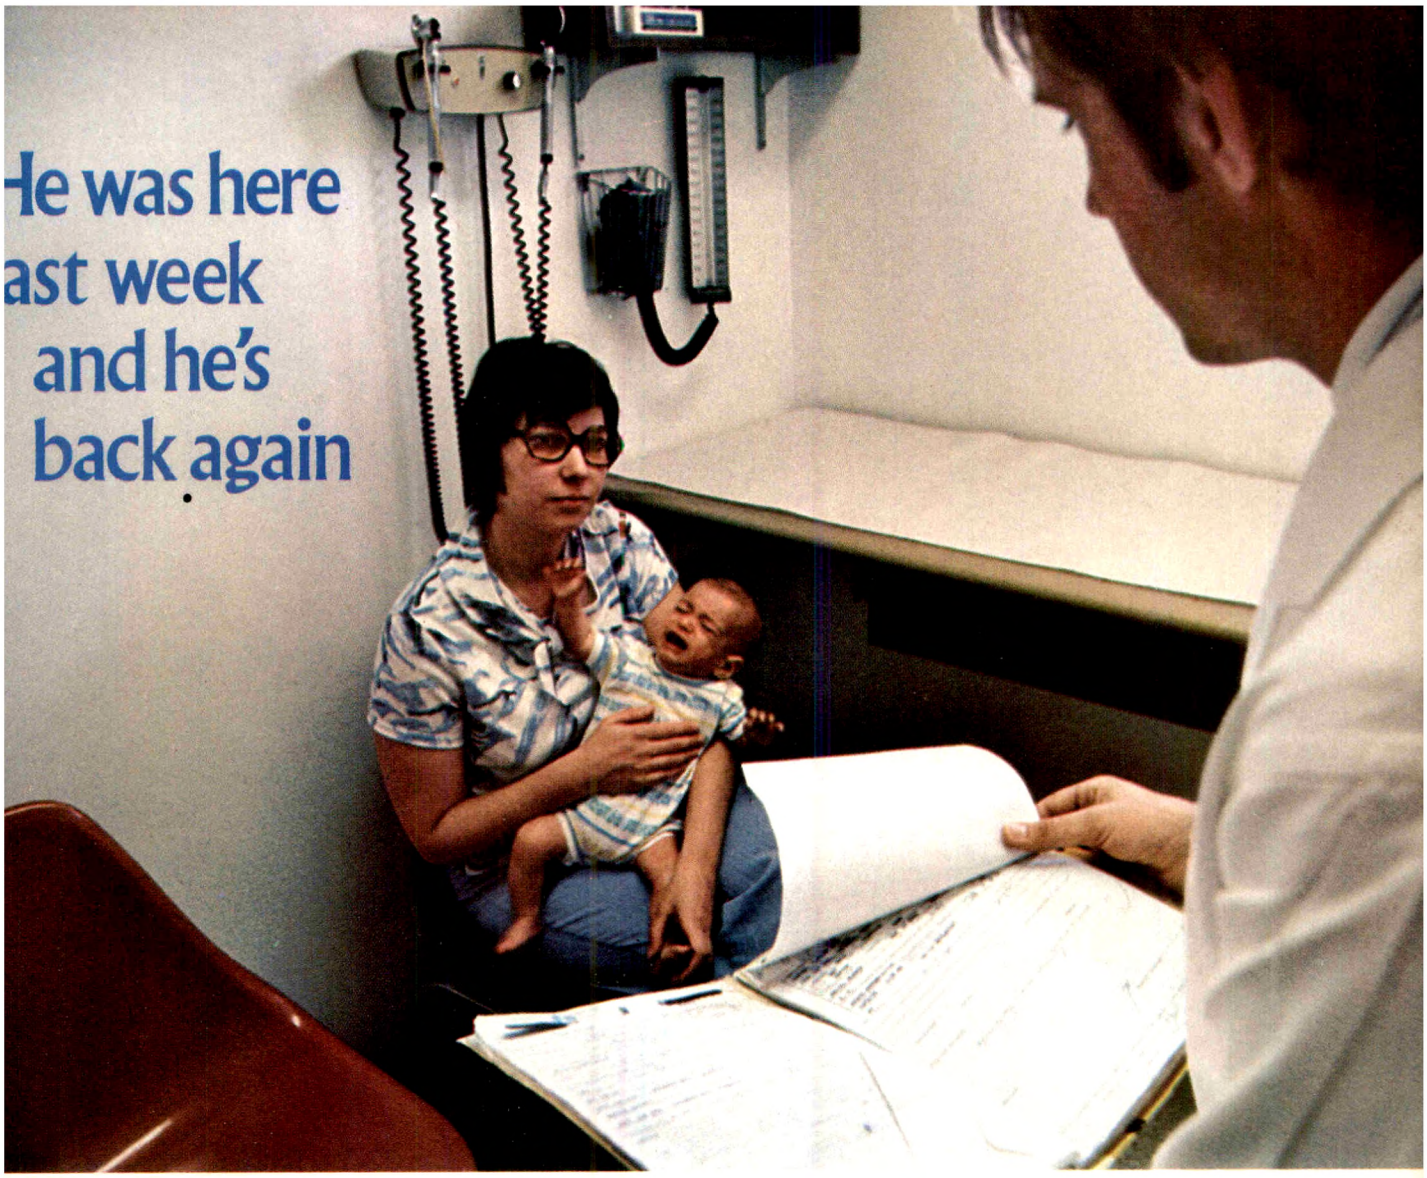
While every precaution is taken to ensure accuracy, we cannot guarantee against the possibility of an occasional change or omission in the preparation of this index.



Have you ruled out cow-milk sensitivity?

The physical symptoms are many and varied: diarrhea, colic, eczema, asthma, vomiting, bronchitis, rhinitis. They can be coupled with behavioral symptoms: repeated refusal of the nursing bottle . . . general fussiness.[1-3]

Alone or together, the manifestations of milk sensitivity are an unnecessary burden for the infant . . . and parents. More important, if unchecked the allergic syndromes can lead to failure to thrive and other serious health problems.[4]

With Isomil® Soy Protein Formula you can avoid the symptoms of milk sensitivity and help confirm your initial diagnosis.

Moreover, Isomil promotes normal growth.[2,5] It looks like milk, it pours like milk and has a pleasant aroma, which help insure acceptability. Unlike milk, Isomil is lactose free. It avoids the possibility of prolonged or recurring diarrhea caused by lactose intolerance.

Consider the possibility of milk sensitivity when associated symptoms are presented. "A high index of suspicion" is essential to its prompt detection.[2,6]

PAIN GONE

while the antibiotic gets going

An effective adjuvant to systemic antibiotic treatment, AURALGAN promptly relieves the pain and reduces the inflammation of acute otitis media, while the antibiotic of choice fights the infection.

AURALGAN contains the topical analgesic action of benzocaine and antipyrine plus glycerin dehydrated...a decongestant so hygroscopic that it "blots up" excess moisture through the tympanic membrane, for relief of pressure and pain in the middle ear.

BRIEF SUMMARY
(For full prescribing information, see package circular.)
AURALGAN® Otic Solution
Each ml contains:

Antipyrine	54.0 mg
Benzocaine	14.0 mg
Glycerin dehydrated q.s. to	1.0 ml

(contains not more than 1.0% moisture) (also contains oxyquinoline sulfate)
INDICATIONS: *Acute otitis media of various etiologies*
—prompt relief of pain and reduction of inflammation in the congestive and serous stages
—adjuvant therapy during systemic antibiotic administration for resolution of the infection
CONTRAINDICATIONS: Hypersensitivity to any of the components or substances related to them. / In the presence of spontaneous perforation or discharge.
DOSAGE AND ADMINISTRATION: *Acute otitis media:* Instill AURALGAN, permitting the solution to run along the wall of the canal until it is filled. Avoid touching the ear with dropper. Then moisten a cotton pledget with AURALGAN and insert into meatus. Repeat every one to two hours until pain and congestion are relieved.
HOW SUPPLIED: No.1000—AURALGAN® Otic Solution, in package containing 15 ml (½ fl oz) bottle with separate dropper-screw cap attachment.

...in acute otitis media

Auralgan®

OTIC SOLUTION

FULLY COMPATIBLE WITH SYSTEMIC ANTIBACTERIAL THERAPY. ON PRESCRIPTION ONLY.

We've been delivering for four generations--and still cost less.

Carnation Evaporated Milk formulas have been raising strong, healthy babies since 1899—delivering the good, sound, natural nutrition newborns and infants thrive on. You see, Carnation Evaporated Milk has naturally-occurring protein with all other nutrients intact. You indicate vitamins, iron, and carbohydrates to meet each baby's needs. Importantly, bottle for bottle, a whole formula made with Carnation Evaporated Milk still costs new mothers less than any proprietary formula. Carnation Evaporated Milk... for four generations. The babies under your care will thrive on it, too.

FREE! Send for your sample copy of the informative patient-oriented booklet: "Preparing Your Baby's Formula." Mail to: Carnation Company, P.O. Box 550, Dept. OB, Pico Rivera, CA 90665.

Why upset a feverish child's stomach with aspirin?

A child's complaints of nausea and stomachache may be a consequence of aspirin therapy. It has been clinically documented that therapeutic doses of aspirin may cause G.I. problems ranging from minor upset[1-3] to serious, but less frequent, ulceration and gastric hemorrhage.[4,5]

Why complicate fever therapy with gastric problems? With Children's TYLENOL you can effectively reduce his fever with virtually no G.I. risk.[6,7]

Advertising Principles: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request.

Subscription Rates: The yearly rates for the AMERICAN JOURNAL OF DISEASES OF CHILDREN is as follows: for members of the AMA, $1.50, included in the annual membership dues; for nonmembers, $24 for one year, $40 for two years in the United States and US possessions; all other countries, $34 for one year, $60 for two years. Special yearly price to residents, interns, and medical students in the United States and US possessions, one year, $12; two years, $20. Address all subscription communications to Circulation-Fulfillment Department. Phone: 312, 751-6079.

Change of Address: POSTMASTER, send address changes to Helen R. Mazur, Director, Circulation-Fulfillment. Notification of address changes should be sent at least six weeks in advance, including both old and new address, and a mailing label taken from the most recent copy. Include your new zip code number.

AMERICAN JOURNAL OF DISEASES OF CHILDREN (ISSN 0002-922X) is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago and at additional mailing office.

ACTIFED-C® Expectorant ℂ

Each 5 cc teaspoonful contains: codeine phosphate 10 mg (Warning—may be habit-forming); Actidil® brand triprolidine HCl 2 mg; Sudafed® brand pseudoephedrine HCl 30 mg; guaifenesin 100 mg. Preservatives are methylparaben 0.1% and sodium benzoate 0.1%.

With the cough-stopping power of codeine.

Controls Excessive Coughing Without Preventing Productive Expectoration

Persistent, repetitive, dry coughs can be a problem in the pediatric patient, particularly at night when it often disturbs sleep. Actifed-C is made for this type of cough.

It contains codeine to reduce severity and persistence plus guaifenesin to liquefy and ease the expulsion of mucus. Moreover, Actifed-C is the only cough medication that contains triprolidine and pseudoephedrine... the decongestant/antihistamine combination that has been part of the NASA Space Medicine Kit since 1968.

Indications: Based on a review of this drug by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indications as follows:

"Lacking substantial evidence of effectiveness as a fixed combination": For the symptomatic relief of cough in conditions such as: the common cold, acute bronchitis, allergic asthma, bronchiolitis, croup, emphysema, tracheobronchitis.

Final classification of the less-than-effective indications requires further investigation.

Warning: Use in Pregnancy: Experience with this drug in pregnant women is inadequate to determine whether there exists a potential for harm to the developing fetus.

Precautions: Although pseudoephedrine hydrochloride causes virtually no pressor effect in normotensive patients, it should be used with caution in patients with hypertension. In addition, even though triprolidine hydrochloride produces only a low incidence of drowsiness, appropriate precautions should be observed.

Side Effects: The great majority of patients will not have any side effects. Only certain patients, sensitive to one or another of the ingredients, may note mild stimulation or mild sedation.

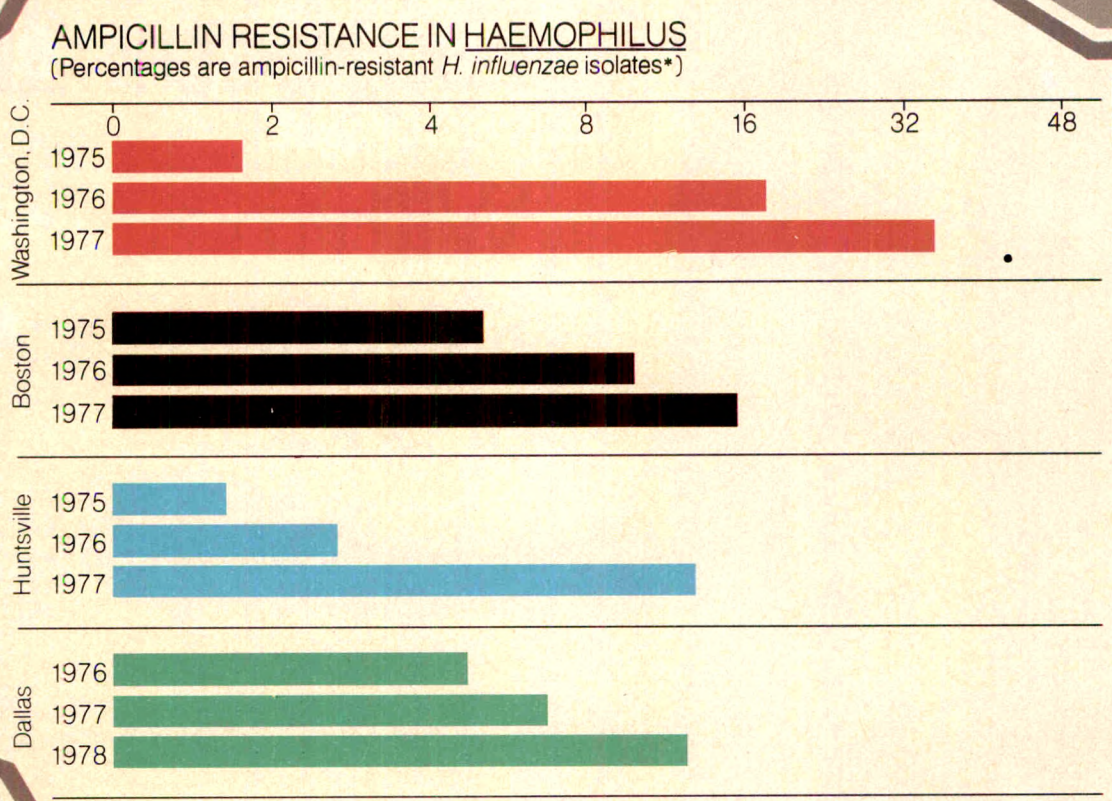
Supplied: Bottles of 1 pint. Complete literature available on request from Professional Services Dept. PML.

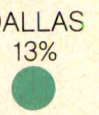
Not recommended for use in children under 2 years of age.

ONE HUNDRED YEARS WELLCOME

Burroughs Wellcome Co.
Research Triangle Park
North Carolina 27709

Increasing resistance of





Brief Summary.
Consult the package literature for prescribing information.

Indications and Usage: Ceclor®(cefaclor, Lilly) is indicated in the treatment of the following infections when caused by susceptible strains of the designated microorganisms:
Otitis media caused by *Streptococcus pneumoniae (Diplococcus pneumoniae), Haemophilus influenzae,* staphylococci, and *S. pyogenes* (group A beta-hemolytic streptococci).
Appropriate culture and susceptibility studies should be performed to determine susceptibility of the causative organism to Ceclor.

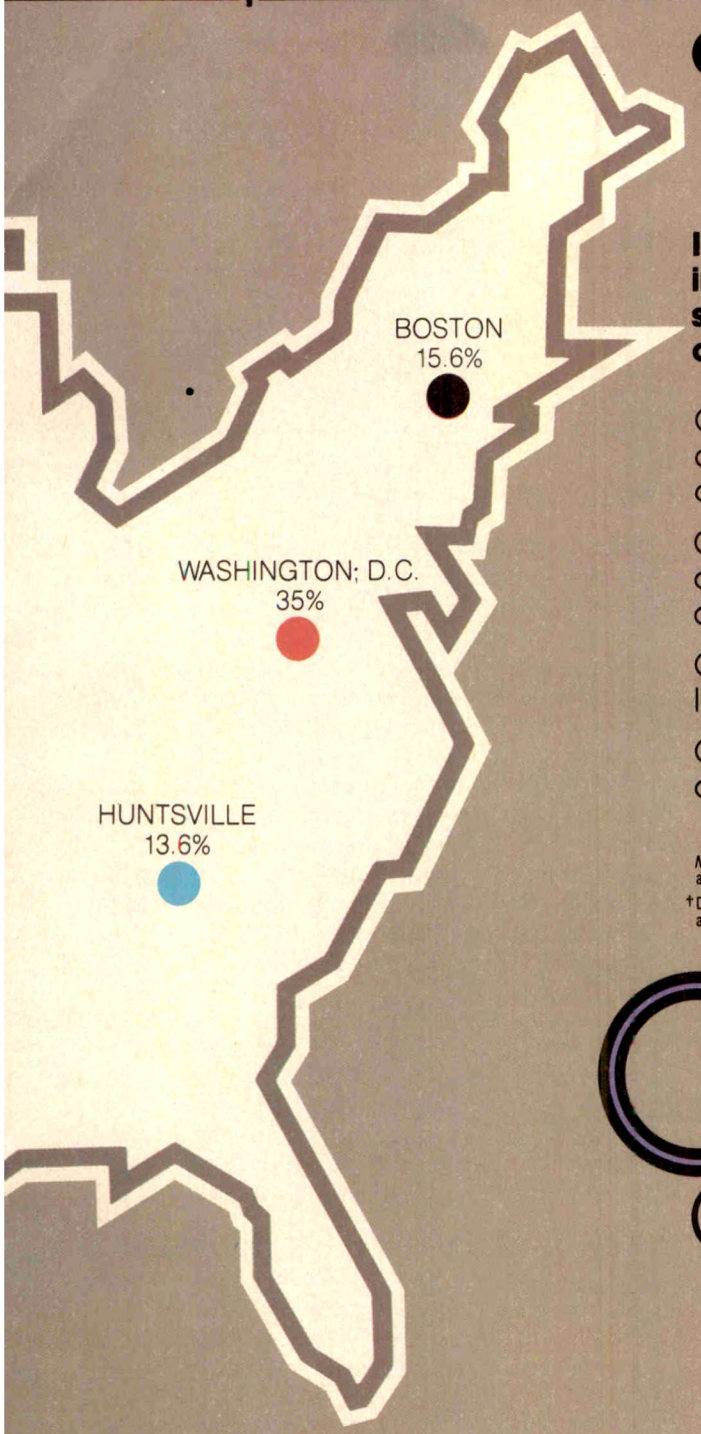
Contraindication: Ceclor is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

Warnings: IN PENICILLIN-SENSITIVE PATIENTS, CEPHALOSPORIN ANTIBIOTICS SHOULD BE ADMINISTERED CAUTIOUSLY. THERE IS CLINICAL AND LABORATORY EVIDENCE OF PARTIAL CROSS-ALLERGENICITY OF THE PE CILLINS AND THE CEPHALOSPORINS, AND THERE ARE INSTANCES IN WHICH PATIENTS HAVE HAD REACTIONS TO BOTH DRUG CLASSES (INC ING ANAPHYLAXIS AFTER PARENTERAL USE).
Antibiotics, including Ceclor® (cefaclor, Lilly), shoul administered cautiously to any patient who has demon strated some form of allergy, particularly to drugs.

Precautions: If an allergic reaction to cefaclor occurs, t drug should be discontinued, and, if necessary, the pa should be treated with appropriate agents, e.g., presso amines, antihistamines, or corticosteroids.
Prolonged use of cefaclor may result in the overgrow of nonsusceptible organisms. Careful observation of th patient is essential. If superinfection occurs during therapy, appropriate measures should be taken.
Positive direct Coombs tests have been reported dur treatment with the cephalosporin antibiotics. In hemat logic studies or in transfusion cross-matching procedu when antiglobulin tests are performed on the minor sid in Coombs testing of newborns whose mothers have received cephalosporin antibiotics before parturition, i

Haemophilus influenzae in otitis media...

a valid concern



In many areas of the country, increasing numbers of *H. influenzae* show resistance to conventional antibiotic therapy.[1-3]

Ceclor is effective in the treatment of otitis media†, including that due to some ampicillin-resistant strains of *H. influenzae*.[4-9]

Ceclor has been shown to be clinically and bacteriologically effective in treating otitis media due to susceptible organisms.[10]

Ceclor is available in two pleasant-tasting liquids.

Ceclor provides effective single-agent antibiotic therapy for otitis media.

Note: Ceclor is contraindicated in patients with known allergy to the cephalosporins and should be given cautiously to penicillin-allergic patients.

† Due to susceptible strains of *Streptococcus pneumoniae*, *H. influenzae*, staphylococci, and *S. pyogenes*.

125-mg/5-ml and 250-mg/5-ml oral suspensions

Ceclor®

cefaclor

should be recognized that a positive Coombs test may be due to the drug.

Ceclor® (cefaclor, Lilly) should be administered with caution in the presence of markedly impaired renal function. Under such a condition, careful clinical observation and laboratory studies should be made because safe dosage may be lower than that usually recommended.

Usage in Pregnancy—Although no teratogenic or antifertility effects were seen in reproduction studies in mice and rats receiving up to 12 times the maximum human dose or in ferrets given three times the maximum human dose, the safety of this drug for use in human pregnancy has not been established. The benefits of the drug in pregnant women should be weighed against a possible risk to the fetus.

Usage in Infancy—Safety of this product for use in infants less than one month of age has not been established.

Adverse Reactions: In clinical studies in 1493 patients, adverse effects considered related to cefaclor therapy were uncommon and are listed below:

Gastrointestinal symptoms occurred in about 2.5 percent of patients and included diarrhea (1 in 70) and nausea and vomiting (1 in 90).

Hypersensitivity reactions were reported in about 1.5 percent of patients and included morbilliform eruptions (1 in 100). Pruritus, urticaria, and positive Coombs tests each occurred in less than 1 in 200 patients.

Other effects considered related to therapy included eosinophilia (1 in 50 patients) and genital pruritus or vaginitis (less than 1 in 100 patients).

Causal Relationship Uncertain—Transitory abnormalities in clinical laboratory test results have been reported. Although they were of uncertain etiology, they are listed below to serve as alerting information for the physician.

Hepatic—Slight elevations in SGOT, SGPT, or alkaline phosphatase values (1 in 40).

Hematopoietic—Transient fluctuations in leukocyte count, predominantly lymphocytosis occurring in infants and young children (1 in 40).

Renal—Slight elevations in BUN or serum creatinine (less than 1 in 500) or abnormal urinalysis (less than 1 in 200).

Instructions for Authors

General Information.—Send manuscripts by first-class (**not** registered) mail to the Chief Editor, Gilbert B. Forbes, MD, Box 777, 601 Elmwood Ave, Rochester, NY 14642. Designate one author as correspondent and provide his/her address and telephone number. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the *American Journal of Diseases of Children* and may not be published elsewhere without permission from the publisher (AMA).

In view of the provisions of *The Copyright Revision Act of 1976*, effective Jan 1, 1978, the author(s) of manuscripts, letters to the editor, and book reviews accepted for publication in the JOURNAL will be required to sign and date the following statement: "In consideration of the AMA taking action in reviewing and editing my/our submission, the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the AMA in the event that such work is published by the AMA."

Manuscript Preparation.—All the elements of a manuscript must be submitted in **triplicate, double-spaced throughout**. Use heavy-duty white bond paper, 21.6 × 27.9 cm, and 2.5-cm margins. If a word processor is used, do not justify lines. The style of writing should conform to proper English usage and syntax. All measurements are to be in metric units, temperatures in Centigrade.

All accepted manuscripts are subject to copy editing. The corresponding author will receive an edited typescript and layout for approval. Forms for ordering reprints are included with the edited typescript. Proofs will be sent for approval if requested by the author and if printing deadlines permit. The author is responsible for all statements in his/her work, including changes made by the copy editor.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines. The title page should include the full names and academic affiliations of all authors, the address to which requests for reprints should be sent, and, if the manuscript was presented at a meeting, the name of the organization, place, and date on which it was read.

Abstract.—Provide an abstract (135-word maximum) of the article, including statement of the problem, method of study, results, and conclusions. The abstract replaces the summary.

Informed Consent.—Manuscripts reporting the results of experimental investigations on humans must include a statement to the effect that informed consent was obtained from the parents or guardians after the nature of the procedure(s) had been fully explained.

Clinical Memoranda.—Brief accounts of interesting observations and clinical situations. Limited to 800 words plus one table or illustration; abstract unnecessary. Submit in triplicate, double-spaced. Copyright assignment required.

Letters to the Editor.—Correspondence pertaining to material published in the JOURNAL. Limit 500 words. Submit in triplicate, double-spaced, and clearly marked "For publication." Copyright assignment required.

References.—List in order of their appearance in the text, and type double-spaced, in the following manner:

1. Applebaum MM, Thaler MM: Reye syndrome without initial hepatic involvement. *Am J Dis Child* 1977; 131:295-296.
2. Koller LR: *Ultraviolet Radiation*, ed 2. New York, John Wiley & Sons, 1965, 141-160.
3. Daughaday WH: The adenohypophysis, in Williams RH (ed): *Textbook of Endocrinology*, ed 5. Philadelphia, WB Saunders, 1974: 31-79.

Do not include unpublished data, personal communications, or manuscripts "in preparation" or "submitted" in the list of references. Such material, if essential, may be incorporated in the body of the article.

Illustrations.—Submit only high-contrast glossy prints in triplicate, unmounted and untrimmed. Preferred size is 12.7 × 17.3 cm (5 × 7 in). Figure number, name of first author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. Lettering must be legible after reduction to column size. Magnification and stain should be provided for histologic sections.

For illustrations in full color submit 35-mm, positive color transparencies, mounted in cardboard and carefully packaged. Do not submit glass-mounted transparencies; do not submit color prints. The fee is $275 for up to six square-finished color illustrations that can be arranged on one page. A letter of intent to pay the fee must accompany submission.

Legends.—Legends for illustrations should be typed double-spaced, beginning on a separate sheet of paper (40-word maximum for each).

Acknowledgments.—Illustrations and tables from other publications must be suitably acknowledged, and accompanied by written permission from publisher and author.

Photographic Consents.—A signed statement of consent from **both** parents (or guardian) or the persons involved must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 21.6 × 27.9 cm paper. If a table must be continued, use a second sheet and repeat all heads. Each table must have a title.

Uniform Requirements.—Further details on manuscript preparation are given in the document *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* prepared by the International Steering Committee of Medical Editors. Reprints of this document are available by directing requests to this journal: Scientific Publications, 535 N Dearborn St, Chicago, IL 60610.

IEASLES, MUMPS AND RUBELLA
RUS VACCINE, LIVE | MSD)

etter·

ntains rubella virus strain RA 27/3

Convenient

e shot vaccinates against all three:
asles, mumps, rubella

For a brief summary of prescribing information, please see following page.

MSD
MERCK SHARP & DOHME

ht © Merck & Co., Inc., 1980
s reserved.

Indications: *ATTENUVAX® (Measles Virus Vaccine, Live, Attenuated, MSD)* — Active immunization against measles (rubeola) in children 15 months of age or older.
BIAVAX®II (Rubella and Mumps Virus Vaccine, Live, MSD) — Simultaneous immunization against rubella and mumps in children 15 months of age to puberty. May be given as early as 12 months if that offers greater convenience in scheduling.
MERUVAX®II (Rubella Virus Vaccine, Live, MSD) — Immunization against rubella (German measles) in children 15 months of age to puberty. May be given as early as 12 months if that offers greater convenience in scheduling. May be useful for adolescent and adult males to prevent or control rubella outbreaks in circumscribed population groups. In postpubertal females vaccination must not be undertaken unless the woman is not pregnant, is susceptible to rubella (as shown by Hemagglutination Inhibition test), agrees not to become pregnant for next three months (also in immediate postpartum period), and is informed of frequent occurrence of self-limited arthralgia and possible arthritis beginning two to four weeks after vaccination.
M-M-R®II (Measles, Mumps and Rubella Virus Vaccine, Live, MSD) — Simultaneous immunization against measles, mumps, and rubella in children 15 months of age to puberty.
M-R-VAX®II (Measles and Rubella Virus Vaccine, Live, MSD) — Simultaneous immunization against measles (rubeola) and rubella (German measles) in children 15 months of age to puberty.
MUMPSVAX® (Mumps Virus Vaccine, Live, MSD) — Immunization against mumps for children 15 months of age or older and adults. May be given as early as 12 months if that offers greater convenience in scheduling.

Contraindications: Pregnancy or the possibility of pregnancy within three months following vaccination (see special considerations for ATTENUVAX below); hypersensitivity to neomycin; any febrile respiratory illness or other active infection; for measles-containing vaccines, active untreated tuberculosis; therapy with ACTH, corticosteroids (except as replacement therapy, e.g., for Addison's disease), irradiation, alkylating agents, or antimetabolites; blood dyscrasias, leukemia, lymphomas of any type, or other malignant neoplasms affecting the bone marrow or lymphatic systems; primary immunodeficiency states, including cellular immune deficiencies, hypogammaglobulinemic and dysgammaglobulinemic states.

Hypersensitivity to Eggs, Chicken, or Chicken Feathers: For measles- and/or mumps-containing vaccines, in patients hypersensitive to eggs, chicken, or chicken feathers, weigh benefits of immunization against potential risks of hypersensitivity reactions.

Pregnancy: *ATTENUVAX* — The effects of ATTENUVAX on fetal development are unknown at this time. Live attenuated measles virus vaccine should not be given to persons known to be pregnant; furthermore, pregnancy should be avoided for three months following vaccination. Reports have indicated that natural measles during pregnancy enhances fetal risk. Increased rates of spontaneous abortion, stillbirth, congenital defects, and prematurity have been observed subsequent to natural measles during pregnancy. There are no adequate studies of the attenuated (vaccine) strain of measles virus in pregnancy. However, it would be prudent to assume that the vaccine strain of virus is also capable of inducing adverse fetal effects for up to three months following vaccination.
Vaccine administration to postpubertal females entails a potential for inadvertent immunization during pregnancy. Theoretical risks involved should be weighed against the risks that measles poses to the unimmunized adolescent or adult. Advisory committees reviewing this matter have recommended vaccination of postpubertal females who are presumed to be susceptible to measles and not known to be pregnant. If a measles exposure occurs during pregnancy, one should consider the possibility of providing temporary passive immunity through the administration of immune serum globulin (human).

Precautions: Administer subcutaneously; *do not give intravenously.* Epinephrine should be available for immediate use should an anaphylactoid reaction occur. Should not be given less than one month before or after immunization with other *live* virus vaccines, with the exception that ATTENUVAX, MUMPSVAX, and/or MERUVAX II may be administered simultaneously. BIAVAX II may be administered simultaneously with ATTENUVAX. Monovalent or trivalent poliovirus vaccine, live, oral, may be administered simultaneously with ATTENUVAX and/or MUMPSVAX. Vaccinations should be deferred for at least three months following blood or plasma transfusions or administration of more than 0.02 ml human immune serum globulin per pound of body weight. However, rubella vaccine may be given prior to discharge to susceptible postpartum patients who received blood products, provided that a repeat HI titer is drawn six to eight weeks after vaccination to insure seroconversion; similarly, although rubella vaccine may be given in the immediate postpartum period to those nonimmune women who have received anti-Rh_0 (D) immune globulin (human) without interfering with vaccine effectiveness, a follow-up postvaccination HI titer should also be determined.
Attenuated measles, mumps, and rubella virus vaccines, live, given separately, may result in a temporary depression of tuberculin skin sensitivity; therefore, if a tuberculin test is to be done, it should be administered before or simultaneously with any of these virus vaccines. Vaccination may not result in seroconversion in 100 percent of susceptible subjects.
Measles-Containing Vaccines — Due caution should be employed in children with a history of febrile convulsions, cerebral injury, or any other condition in which stress due to fever should be avoided. The physician should be alert to the temperature elevation which may occur 5 to 12 days after vaccination. The occurrence of thrombocytopenia and purpura has been extremely rare.
Rubella-Containing Vaccines — Excretion of live attenuated rubella virus from the nose and throat has occurred in the majority of susceptible individuals 7 to 28 days after vaccination. There is no confirmed evidence to indicate that such virus is transmitted to susceptible persons who are in contact with vaccinated individuals. Consequently, transmission, while accepted as a theoretical possibility, is not regarded as a significant risk.

Adverse Reactions: To date, clinical evaluation of the combination vaccines has revealed those adverse reactions expected to follow administration of the monovalent vaccines given separately.
Measles-Containing Vaccines — Occasionally, moderate fever (101–102.9 F); less commonly, high fever (above 103 F); rarely, febrile convulsions. Infrequently, rash, usually minimal without generalized distribution. Reactions at injection site. Local reactions characterized by marked swelling, redness, and vesiculation at the injection site of attenuated live measles virus vaccines have occurred in children who previously received killed measles vaccine; the combination vaccines were not given under this condition in clinical trials.
Experience from more than 80 million doses of all live measles vaccines given in the U.S. through 1975 indicates that significant central nervous system reactions such as encephalitis and encephalopathy, occurring within 30 days after vaccination, have been temporally associated with measles vaccine approximately once for every million doses. In no case has it been shown that reactions were actually caused by vaccine. The Center for Disease Control has pointed out that "a certain number of cases of encephalitis may be expected to occur in a large childhood population in a defined period of time even when no vaccines are administered." However, the data suggest the possibility that some of these cases may have been caused by measles vaccines. The risk of such serious neurological disorders following live measles virus vaccine administration remains far less than that for encephalitis and encephalopathy with natural measles (one per thousand reported cases). There have been reports of subacute sclerosing panencephalitis (SSPE) in children who did not have a history of natural measles but did receive measles vaccine. Some of these cases may have resulted from unrecognized measles in the first year of life or possibly from the measles vaccination. Based on estimated nationwide measles vaccine distribution, the association of SSPE cases to measles vaccination is about one case per million vaccine doses distributed, far less than the 5 to 10 cases of SSPE per million cases of natural measles.
Rubella-Containing Vaccines — Adverse reactions include malaise, sore throat, headache, fever, and rash; mild local reactions such as erythema, local pain, induration, tenderness, and regional lymphadenopathy; thrombocytopenia and purpura; allergic reactions such as urticaria; and arthritis, arthralgia that is infrequently associated with signs of inflammation, and polyneuritis.
Moderate fever (101–102.9 F) occurs occasionally, and high fever (103 F) occurs less commonly. Rash occurs infrequently and is usually minimal without generalized distribution. Encephalitis and other nervous system reactions have occurred very rarely.
Transient arthritis, arthralgia, and polyneuritis vary in frequency and severity with age and sex, being greatest in adult females and least in prepubertal children. In children, joint reactions are rare and of brief duration if they do occur. In women, incidence rates for arthritis and arthralgia are generally higher than those seen in children (children: 0–3 percent; women: 12–20 percent), and the reactions tend to be more marked and of longer duration. Rarely, symptoms may persist for a matter of months. In adolescent girls, the reactions appear to be intermediate in incidence between those seen in children and in adult women. Even in older women (35–45 years), these reactions are generally well tolerated and rarely interfere with normal activities.
Mumps-Containing Vaccines — Parotitis and orchitis. Rarely, purpura and allergic reactions such as urticaria. Very rarely, encephalitis and other nervous system reactions. With the monovalent mumps vaccine, mild fever occurs occasionally, and fever above 103 F is uncommon.

Shipment, Storage, and Reconstitution: During shipment, to insure that there is no loss of potency, the vaccine must be maintained at a temperature of 10 C (50 F) or less. Before reconstitution, store vaccines at 2–8 C (35.6–46.4 F) and *protect from light.* Use only diluent supplied to reconstitute vaccines. If not used immediately, store reconstituted vaccines in a dark place at 2–8 C (35.6–46.4 F), and discard if not used within eight hours. Use a separate sterile syringe and needle for each individual patient to prevent transmission of infectious agents from one person to another.
Color: The color of the vaccine when reconstituted is yellow. ATTENUVAX is acceptable for use only if clear.

How Supplied: *ATTENUVAX® (Measles Virus Vaccine, Live, Attenuated, MSD)* — Single-dose vials of lyophilized vaccine, containing when reconstituted not less than the equivalent of 1,000 $TCID_{50}$ (tissue culture infectious doses) of measles virus vaccine expressed in terms of the assigned titer of the FDA Reference Measles Virus, and approximately 25 mcg neomycin.
BIAVAX®II (Rubella and Mumps Virus Vaccine, Live, MSD) — Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than 1,000 $TCID_{50}$ of rubella virus vaccine, live, and 5,000 $TCID_{50}$ of mumps virus vaccine, live, expressed in terms of the assigned titer of the FDA Reference Rubella and Mumps Viruses, and approximately 25 mcg neomycin.
MERUVAX®II (Rubella Virus Vaccine, Live, MSD) — Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than the equivalent of 1,000 $TCID_{50}$ of rubella virus vaccine expressed in terms of the assigned titer of the FDA Reference Rubella Virus, and approximately 25 mcg neomycin.
M-M-R®II (Measles, Mumps and Rubella Virus Vaccine, Live, MSD) — Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than 1,000 $TCID_{50}$ of measles virus vaccine, live, attenuated, 5,000 $TCID_{50}$ of mumps virus vaccine, live, and 1,000 $TCID_{50}$ of rubella virus vaccine, live, expressed in terms of the assigned titer of the FDA Reference Measles, Mumps, and Rubella Viruses, and approximately 25 mcg neomycin.
M-R-VAX®II (Measles and Rubella Virus Vaccine, Live, MSD) — Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than 1,000 $TCID_{50}$ of measles virus vaccine, live, attenuated, and 1,000 $TCID_{50}$ of rubella virus vaccine, live, expressed in terms of the assigned titer of the FDA Reference Measles and Rubella Viruses, and approximately 25 mcg neomycin.
MUMPSVAX® (Mumps Virus Vaccine, Live, MSD) — Single-dose vials of lyophilized vaccine, containing when reconstituted not less than 5,000 $TCID_{50}$ of mumps virus vaccine expressed in terms of the assigned titer of the FDA Reference Mumps Virus, and approximately 25 mcg neomycin.
Each of these vaccines is supplied as a single-dose vial with a disposable syringe containing diluent and fitted with a 25-gauge, 5/8" needle, and as a box of 10 single-dose vials with an accompanying box of 10 diluent-containing disposable syringes with affixed needles.

a chance for a better life with Depakene®
Valproic Acid

For your patients with mixed seizures including absence, or pure absence

Effective seizure control[1] without cosmetic disfigurement

In 28 studies of patients with mixed grand mal and absence, 76% of all patients gained significant improvement; over one-third became seizure-free. In 60 studies involving pure absence, 86% of patients were improved; half became seizure-free.

While serious side effects, including fatal hepatitis, have occurred, the most common side effect with Depakene is G.I. upset, which usually responds to temporary dosage reduction. Problem sedation is not common and cosmetic stigmata such as gum hypertrophy and hirsutism do not occur.

A widely useful anticonvulsant

Depakene is indicated as sole or adjunctive therapy in both simple and complex absence seizures. It is also indicated for adjunctive treatment of patients with multiple seizure types which include absence. Clinical response has been especially noteworthy among patients with generalized tonic-clonic attacks, or with minor motor seizures (e.g., myoclonic movements, akinetic seizures), where combined with absence.

Offering your patients a chance for a better life

Sustained freedom from seizures can mean a drivers license, an active social schedule, involvement in athletic competition—a better life for your patient.

1. Worldwide studies of Depakene experience (Data refer only to grand mal and/or absence seizures. Since each type was evaluated separately, some patients appear in both groups. Though most of these studies were uncontrolled and had widely differing protocols, their collective data clearly support efficacy of the drug).

See overleaf for prescribing information

Depakene®
Valproic Acid Capsules 250 mg
250 mg/5 ml syrup

Depakene®
Valproic Acid

Offering a chance for a better life for your patients with mixed seizures including absence, or pure absence

A BRIEF SUMMARY OF PRESCRIBING INFORMATION

INDICATIONS: DEPAKENE (valproic acid) is indicated for use as sole and adjunctive therapy in the treatment of simple and complex absence seizures, including petit mal. DEPAKENE may also be used adjunctively in patients with multiple seizure types which include absence seizures.

In accordance with the International Classification of Seizures, simple absence is defined as very brief clouding of the sensorium or loss of consciousness (lasting usually 2-15 seconds), accompanied by certain generalized epileptic discharges without other detectable clinical signs. Complex absence is the term used when other signs are also present.

See WARNINGS for statement regarding fatal hepatic dysfunction.

CONTRAINDICATIONS: DEPAKENE (valproic acid) is contraindicated in patients with known hypersensitivity to the drug.

WARNINGS: Hepatic failure resulting in fatalities has occurred in patients receiving DEPAKENE. These incidences usually have occurred during the first six months of treatment with DEPAKENE. Serious or fatal hepatotoxicity may be preceded by non-specific symptoms such as malaise, weakness, lethargy and anorexia. Liver function tests should be performed prior to therapy and at frequent intervals thereafter. Caution should be observed when administering DEPAKENE to patients with pre-existing hepatic disease.

The drug should be discontinued immediately in the presence of significant hepatic dysfunction, suspected or apparent. The frequency of adverse effects (particularly elevated liver enzymes) may increase with increasing dose. Therefore, the benefit gained by increased seizure control by increasing the dosage must be weighed against the increased incidence of adverse effects sometimes seen at higher dosages.

Usage in Pregnancy: THE EFFECTS OF DEPAKENE IN HUMAN PREGNANCY ARE UNKNOWN. ANIMAL STUDIES HAVE DEMONSTRATED TERATOGENICITY.

Studies in rats and human females demonstrated placental transfer of the drug. Doses greater than 65 mg/kg/day given to pregnant rats and mice produced skeletal abnormalities in the offspring, primarily involving ribs and vertebrae; doses greater than 150 mg/kg/day given to pregnant rabbits produced fetal resorptions and (primarily) soft-tissue abnormalities in the offspring. In rats a dose-related delay in the onset of parturition was noted. Postnatal growth and survival of the progeny were adversely affected, particularly when drug administration spanned the entire gestation and early lactation period.

THERE ARE MULTIPLE REPORTS IN THE CLINICAL LITERATURE WHICH INDICATE THAT THE USE OF ANTICONVULSANT DRUGS DURING PREGNANCY RESULTS IN AN INCREASED INCIDENCE OF BIRTH DEFECTS IN THE OFFSPRING. ALTHOUGH DATA ARE MORE EXTENSIVE WITH RESPECT TO TRIMETHADIONE, PARAMETHADIONE, PHENYTOIN, AND PHENOBARBITAL, REPORTS INDICATE A POSSIBLE SIMILAR ASSOCIATION WITH THE USE OF OTHER ANTICONVULSANT DRUGS. THEREFORE, ANTICONVULSANT DRUGS SHOULD BE ADMINISTERED TO WOMEN OF CHILDBEARING POTENTIAL ONLY IF THEY ARE CLEARLY SHOWN TO BE ESSENTIAL IN THE MANAGEMENT OF THEIR SEIZURES.

Anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases where the severity and frequency of the seizure disorder are such that the removal of medication does not pose a serious threat to the patient, discontinuation of the drug may be considered prior to and during pregnancy, although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus.

The prescribing physician will wish to weigh these considerations in treating or counseling epileptic women of childbearing potential.

PRECAUTIONS: *Hepatic dysfunction:* See WARNINGS.

General: Because of reports of thrombocytopenia and platelet aggregation dysfunction, platelet counts and bleeding time determination are recommended before initiating therapy and at periodic intervals. It is recommended that patients receiving DEPAKENE be monitored for platelet count prior to planned surgery. Clinical evidence of hemorrhage, bruising or a disorder of hemostasis/coagulation is an indication for reduction of DEPAKENE dosage or withdrawal of therapy pending investigation.

Since DEPAKENE (valproic acid) may interact with concurrently administered anticonvulsant drugs, periodic serum level determinations of concomitant anticonvulsant drugs are recommended during the early course of therapy. (See Drug Interactions).

DEPAKENE is partially eliminated in the urine as a keto-metabolite which may lead to a false interpretation of the urine ketone test.

Information For Patients: Since DEPAKENE may produce CNS depression, especially when combined with another CNS depressant (e.g., alcohol), patients should be advised not to engage in hazardous occupations, such as driving an automobile or operating dangerous machinery, until it is known that they do not become drowsy from the drug.

Drug Interactions: DEPAKENE may potentiate the CNS depressant activity of alcohol.

THERE IS EVIDENCE THAT DEPAKENE CAN CAUSE AN INCREASE IN SERUM PHENOBARBITAL LEVELS BY IMPAIRMENT OF NON-RENAL CLEARANCE. THIS PHENOMENON CAN RESULT IN SEVERE CNS DEPRESSION. THE COMBINATION OF DEPAKENE AND PHENOBARBITAL HAS ALSO BEEN REPORTED TO PRODUCE CNS DEPRESSION WITHOUT SIGNIFICANT ELEVATIONS OF BARBITURATE OR VALPROATE SERUM LEVELS. ALL PATIENTS RECEIVING CONCOMITANT BARBITURATE THERAPY SHOULD BE CLOSELY MONITORED FOR NEUROLOGICAL TOXICITY. SERUM BARBITURATE LEVELS SHOULD BE OBTAINED, IF POSSIBLE, AND THE BARBITURATE DOSAGE DECREASED, IF APPROPRIATE.

Primidone is metabolized into a barbiturate and, therefore, may also be involved in a similar or identical interaction.

THERE HAVE BEEN REPORTS OF BREAKTHROUGH SEIZURES OCCURRING WITH THE COMBINATION OF DEPAKENE AND PHENYTOIN. MOST REPORTS HAVE NOTED A DECREASE IN TOTAL PLASMA PHENYTOIN CONCENTRATION. HOWEVER, INCREASES IN TOTAL PHENYTOIN SERUM CONCENTRATION HAVE BEEN REPORTED. AN INITIAL FALL IN TOTAL PHENYTOIN LEVELS WITH SUBSEQUENT INCREASE IN PHENYTOIN LEVELS HAS ALSO BEEN REPORTED. IN ADDITION, A DECREASE IN TOTAL SERUM PHENYTOIN WITH AN INCREASE IN THE FREE VS. PROTEIN BOUND PHENYTOIN LEVELS HAS BEEN REPORTED. THE DOSAGE OF PHENYTOIN SHOULD BE ADJUSTED AS REQUIRED BY THE CLINICAL SITUATION.

THE CONCOMITANT USE OF VALPROIC ACID AND CLONAZEPAM MAY PRODUCE ABSENCE STATUS.

Caution is recommended when DEPAKENE (valproic acid) is administered with drugs affecting coagulation, e.g., aspirin and warfarin. (See ADVERSE REACTIONS).

There have been reports of altered thyroid function tests associated with DEPAKENE. The clinical significance of these is unknown.

Carcinogenesis, Mutagenesis: There has been insufficient study of the drug in animals to determine whether it has carcinogenic potential. Carcinogenicity studies in rats and mice are currently in progress.

Mutagenesis studies on DEPAKENE have been performed using bacterial and mammalian systems. These studies have provided no evidence of a mutagenic potential for DEPAKENE.

Pregnancy: See WARNINGS.

Nursing Mothers: DEPAKENE is excreted in breast milk. Concentrations in breast milk have been reported to be 1-10% of serum concentrations. It is not known what effect this would have on a nursing infant. As a general rule, nursing should not be undertaken while a patient is receiving DEPAKENE.

Fertility: Chronic toxicity studies in juvenile and adult rats and dogs demonstrated reduced spermatogenesis and testicular atrophy at doses greater than 200 mg/kg/day in rats and greater than 90 mg/kg/day in dogs. Segment I fertility studies in rats have shown doses up to 350 mg/kg/day for 60 days to have no effect on fertility. THE EFFECT OF DEPAKENE (VALPROIC ACID) ON THE DEVELOPMENT OF THE TESTES AND ON SPERM PRODUCTION AND FERTILITY IN HUMANS IS UNKNOWN.

ADVERSE REACTIONS: Since DEPAKENE (valproic acid) has usually been used with other anticonvulsant drugs, it is not possible, in most cases, to determine whether the following adverse reactions can be ascribed to DEPAKENE alone, or the combination of drugs.

Gastrointestinal: The most commonly reported side effects at the initiation of therapy are nausea, vomiting and indigestion. These effects are usually transient and rarely require discontinuation of therapy. Diarrhea, abdominal cramps and constipation have been reported. Both anorexia with some weight loss and increased appetite with weight gain have also been reported.

CNS Effects: Sedative effects have been noted in patients receiving valproic acid alone but are found most often in patients receiving combination therapy. Sedation usually disappears upon reduction of othe anticonvulsant medication. Ataxia, headache, nystagmus, diplopi asterixis, "spots before eyes", tremor, dysarthria, dizziness, and incoo dination have rarely been noted. Rare cases of coma have been noted patients receiving valproic acid alone or in conjunction with phenoba bital.

Dermatologic: Transient increases in hair loss have been observe Skin rash and petechiae have rarely been noted.

Psychiatric: Emotional upset, depression, psychosis, aggression, h peractivity and behavioral deterioration have been reported.

Musculoskeletal: Weakness has been reported.

Hematopoietic: Thrombocytopenia has been reported. Valproic ac inhibits the secondary phase of platelet aggregation. (See DRUG IN TERACTIONS). This may be reflected in altered bleeding time. Bruisin hematoma formation and frank hemorrhage have been reported. Relativ lymphocytosis and hypofibrinogenemia have been noted. Leukopenia an eosinophilia have also been reported.

Hepatic: Increases in serum alkaline phosphatase and elevations serum glutamic oxaloacetic transaminase (SGOT) have been note Elevation of SGOT may be dose related. Elevations of SGPT and LD have been noted less frequently. Isolated cases of severe hepatotoxicit have been reported but do not appear dose related. (See WARNINGS)

Endocrine: There have been reports of irregular menses and secondar amenorrhea occurring in patients receiving DEPAKENE.

Pancreatic: There have been reports of acute pancreatitis occurring patients receiving DEPAKENE.

OVERDOSAGE: Overdosage with valproic acid may result in dee coma.

Since DEPAKENE is absorbed very rapidly, the value of gastric evacua tion will vary with the time since ingestion. General supportive measure should be applied with particular attention being given to the mainte nance of adequate urinary output.

Naloxone has been reported to reverse the CNS depressant effects DEPAKENE overdosage. Because naloxone could theoretically also revers the anticonvulsant effects of DEPAKENE it should be used with caution.

DOSAGE AND ADMINISTRATION: DEPAKENE (valproic acid) administered orally. The recommended initial dose is 15 mg/kg/day, in creasing at one week intervals by 5 to 10 mg/kg/day, until seizures ar controlled or side effects preclude further increases. The maximu recommended dosage is 60 mg/kg/day. If the total daily dose exceed 250 mg, it should be given in a divided regimen.

The following table is a guide for the initial daily dose of DEPAKEN (valproic acid) (15 mg/kg/day):

Weight (kg)	Weight (lb)	Total Daily Dose (mg)	Number of Capsules or Teaspoonfuls of Syrup Dose 1	Dose 2	Dose 3
10 — 24.9	22 — 54.9	250	0	0	1
25 — 39.9	55 — 87.9	500	1	0	1
40 — 59.9	88 — 131.9	750	1	1	1
60 — 74.9	132 — 164.9	1,000	1	1	2
75 — 89.9	165 — 197.9	1,250	2	1	2

The frequency of adverse effects (particularly elevated liver enzymes may increase with increasing dose. Therefore, the benefit gained by in creased seizure control by increased dosage must be weighed against th increased incidence of adverse effects sometimes seen at higher doses

A good correlation has not been established between daily dose, serur level and therapeutic effect, however, therapeutic serum levels for mos patients will range from 50 to 100 mcg/ml. Occasional patients may b controlled with serum levels lower or higher than this range.

As the DEPAKENE dosage is titrated upward, blood levels of pheno barbital and/or phenytoin may be affected. (See PRECAUTIONS).

Patients who experience G.I. irritation may benefit from administra tion of the drug with food or by slowly building up the dose from an initia low level.

THE CAPSULES SHOULD BE SWALLOWED WITHOUT CHEWING T AVOID LOCAL IRRITATION OF THE MOUTH AND THROAT.

HOW SUPPLIED: DEPAKENE (valproic acid) is available a orange-colored soft gelatin capsules of 250 mg valproic acid bottles of 100 capsules (**NDC** 0074-5681-13), and as a red syrup containing the equivalent of 250 mg valproic acid per 5 ml as the sodium salt in bottles of 16 ounces (**NDC** 0074-5682-16).

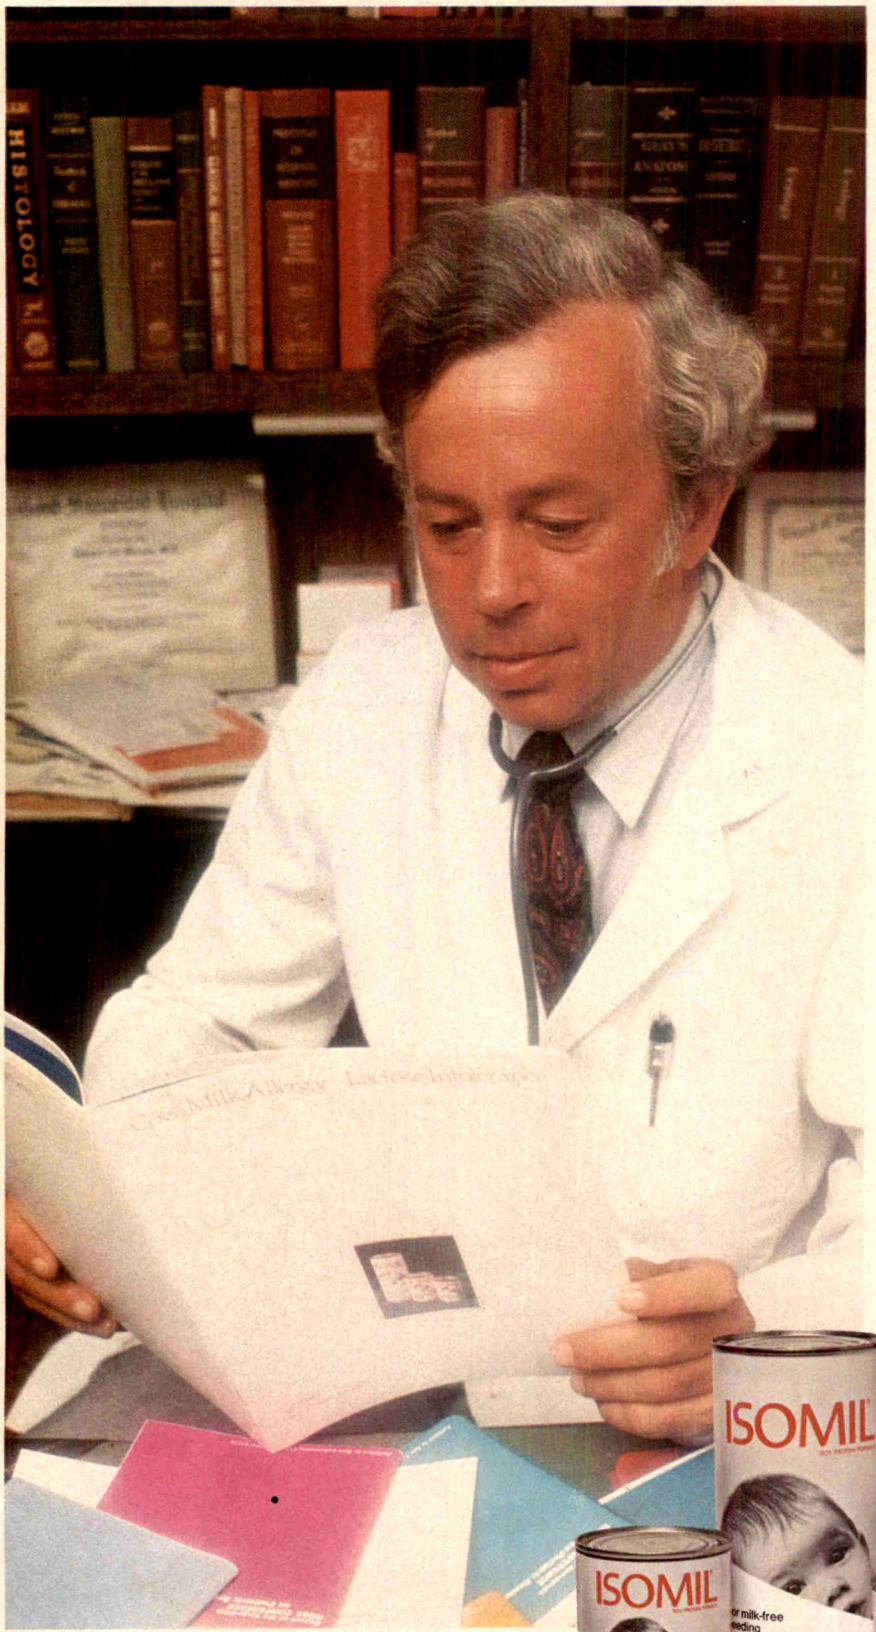
Clinical research is our tradition



What does a tradition of clinical research mean to you? Simply, it means you can recommend Isomil® Soy Protein Formula with confidence that your patients' nutritional needs will be met. One study, for example, documented that infants will grow as rapidly when fed Isomil as those infants fed a cow milk formula.[1] A second study confirmed these findings.[2]

Isomil was also found effective in preventing recurrence of diarrhea due to secondary lactose intolerance. One clinical study found that diarrhea recurrence rates were lower with the group fed Isomil than those fed a milk-based formula.[3] Another study confirmed these findings.[4]

These are four of the studies that have been conducted with Isomil. Clinical research is one reason you can recommend Isomil with confidence: for the infant with a sensitivity to cow milk or with secondary lactose intolerance.

Screening of Newborns for Cystic Fibrosis

The report by Berry et al (see p 930) raises the question of mass screening of newborns for cystic fibrosis (CF). The authors suggest that mass screening is advisable, but do not believe enough data are available to recommend the best procedure. Both of these conclusions may be questioned. The advantages of early diagnosis should be examined. Also, since their article reports the examination of 65,000 meconium specimens, and a collaborative study[1] funded by the National Cystic Fibrosis Foundation reports the examination of more than 100,000 specimens, it should be possible at this point to draw some conclusions about the efficacy of various testing procedures.

It is difficult to argue that the early diagnosis of any disease is not in some way beneficial. However, one may vastly overstate the benefit. This seems to have occurred when Berry et al quoted an estimate "that up to 90% of undiagnosed CF patients died during the first two years of life." The reference[2] is not convincing, as it is from an abstract that refers to another abstract[3] (both read by title alone), neither of which presents any data to support this remarkable conclusion.

If it is assumed that most infant deaths of unknown cause are not due to cystic fibrosis (the disease being usually apparent at the time of autopsy), the benefits of early diagnosis would be to the asymptomatic or mildly symptomatic patient. If treatment of these patients is advantageous, it is fair to ask what specific treatment is helpful. Pancreatic enzymes or a predigested formula given to a patient growing normally despite pancreatic insufficiency will decrease the appetite and make the stools more normal. There is little reason to suspect that enzymes alone would lower morbidity or mortality. Mist tent therapy is not useful.[4] Postural drainage and chest physical therapy cannot be expected to benefit greatly the patient who does not have significant pulmonary disease.

If morbidity and mortality are actually lowered by early diagnosis, it is probably because of therapy with antibiotics. It seems possible that such therapy given early in the course of the disease would be beneficial. This, however, is unproved. One wonders if continuous therapy retards the progress of pulmonary disease. Is intermittent therapy for episodes of productive coughing superior to continuous therapy, or to no therapy? Obviously, controlled prospective studies could answer these questions. One must wonder why they have not been done.

Early diagnosis of CF certainly provides the benefit of genetic counseling at an optimal time. Prior to this study, however, Berry et al found that approximately 50% of the patients in their clinic were diagnosed before 18 months of age. In turn, I and my colleagues reviewed the histories of 88 index cases in our clinic, an index case being defined as the first CF patient diagnosed in a family. The conditions of only 35% of these patients were diagnosed during the first year of life. However, many of those cases not diagnosed during the first year were symptomatic during this period. During their first year, 67% of those not diagnosed had abnormal stools, 40% had a continuous cough, and 33% had both. Of the 88 patients, only 17% were asymptomatic during the first year.

The data from the collaborative study of meconium and from the article of Berry et al can be briefly summarized. In the collaborative study, meconium from 102,159 infants was tested with a paper strip test (BMC Test Strip) according to the instructions. There were 216 positive test results, of which 18 were found to have sweat-test-confirmed CF. Five children with negative test results were later found to have CF.

Mass screening with this test was not recommended. The false-positive result rate of 92% necessitates 12 sweat tests to diagnose one CF patient. Since many centers try to avoid doing sweat tests before 6 weeks of age because of the frequency of inadequate sweating in younger infants, considerable parental anxiety would surely occur during the waiting period. There were five known false-negative results, possibly more. Of those tested, 87% were white. An incidence in whites of 1:2,000 is frequently mentioned, though not proved. Using this incidence, one can calculate that 44 CF patients might have been expected, which suggests a false-negative result rate of 59%.

Berry et al used different, and possibly superior, technology. In 20,490 specimens, all subjects with possibly positive paper strip test results were followed up with a more quantitative test for albumin, radial immunodiffusion. In 44,816 subsequent specimens, the same procedure was followed, but only on those specimens initially positive for lactase. The data are presented in a manner that allows separate analysis of whites, whose incidence of CF is high, and normal-birth-weight infants, whose incidence of false-positive results is low.

When the data of Berry et al on white, normal-birth-weight infants is analyzed, the results seem encouraging. The combination of the paper strip test plus radial immunodiffusion brings the false-positive result rate down to 68%. The false-negative result rate, when all specimens were paper strip tested, and again assuming a 1:2,100 incidence, is only 28%.

Preliminary screening for lactase may have missed some CF patients. The data suggest a false-negative result rate of 68%.

Unfortunately, none of this is significantly different ($P < .2$) from the results of the collaborative study. Data from the collaborative study are not presented in a manner that allows separation of whites and normal-birth-weight infants. If such a separation was possible, it might, or might not, be possible to show that the modification of the paper strip test of Berry et al was a significant improvement. Though the use of the test for lactase as an initial screen seems to increase the false-negative result rate, this result is also not statistically significant.

Although Berry et al suggest further studies, some prediction of the probable results of such studies is possible. Specifically, relatively high rates of false-positive and false-negative results would be expected. The cost-to-benefit ratio would be high.

The basic biochemical defect in CF still eludes us. No serum factor has been identified biochemically, and no biological test for a serum factor is sufficiently accurate to allow confident identification of heterozygotes or homozygotes. Some doubt the existence of a serum factor.[5] With funds for health care increasingly limited, an argument can be made for neglecting meconium and concentrating on basic research. While waiting for the results of such research, the clinician interested in CF and its early diagnosis might encourage continuing medical education. As mentioned, only 17% of our patients were completely asymptomatic during their first year of life.

Minimal Brain Dysfunction and Hyperkinesis

A Clinical Viewpoint

During the last 20 years much attention has been given in the medical and psychological literature to the syndrome of minimal brain dysfunction (MBD) or hyperkinesis (hyperactivity), the terms generally being used interchangeably. Experts have emphasized the high frequency and clinical importance of this condition and have warned clinicians about the necessity of early detection and proper treatment. The conscientious clinician cannot fail to be impressed by the magnitude of this literature and its sense of urgency.

However, when the clinician inspects these reports closely, the concept is found to be so poorly described that deciding whether a particular case fits the definition adequately is difficult. The expert consultant, who is presented with a child with clear evidence of academic or behavioral problems, may label such a case as MBD with little hesitation, but the primary care clinician is often perplexed.

The purposes of this communication are to review critically the recent literature to establish the extent of this uncertainty of definition of MBD and the consequences of this situation and to suggest a solution.

REVIEW OF THE LITERATURE

The extensive literature on MBD can be organized under several headings for review and analysis.

Original Definition

In an effort to update the work of Strauss and Lehtinen,[1] a US Public Health Service task force, under the leadership of Clements, met and published in 1966 a monograph[2] in which they attempted to clarify the mounting confusion by standardizing terminology and providing a definition of

MBD. The committee's definition is as follows:

> Children of near average, average, or above average general intelligence with certain learning or behavioral disabilities ranging from mild to severe, which are associated with deviations of function of the central nervous system. These disabilities may manifest themselves by various combinations of impairment in perception, conceptualization, language, memory and control of attention, impulse, or motor function.

The statement goes on to list a considerable variety of behavioral, cognitive, and neurological findings, which may accompany the syndrome. A striking omission is any mention of the minimum criteria that must be fulfilled to allow the diagnosis to be applied with certainty.

Little help came from the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders (DSM-II).*[3] Their definition offered for the hyperkinetic reaction of childhood is as follows:

> This disorder is characterized by overactivity, restlessness, distractibility, and short attention span, especially in young children; the behavior usually diminishes in adolescence.

Once again no delineation of these characteristics and no set criteria necessary for the diagnosis were offered to the clinician. In the *DSM-III*, to be published in 1980,[4] the hyperkinetic reaction is renamed an "attention deficit disorder." Although the description has now been expanded from three lines to four pages, it fails to achieve necessary clarity, as we shall point out later.

Differentiation of MBD From Normal

A syndrome is usually thought of as a group of abnormal signs and symptoms characterizing a disease state, such as the sore throat, fever, and positive throat culture that define a streptococcal pharyngitis. It is difficult to understand, therefore, how the behavioral syndrome said to characterize MBD can be diagnosed, since not one of the experts writing about MBD has instructed us as to where the normal leaves off and the abnormal begins. The traits of high activity, high distractibility, and low persistence (or attention span) are temperamental characteristics that have been demonstrated by Thomas et al[5,6] to exist in the general population and are found in children who do not have problems in school adjustment.[7] If 50% of the population is by definition more active than the mean, how active must a child be to be labelled as hyperactive or hyperkinetic? How is this to be measured and by whom? If it is not the quantity of the activity but the quality, what is that quality that is the real problem?

Furthermore, not only are the behaviors in the MBD syndrome poorly differentiated from normal characteristics, but some of the other components of the syndrome are considered abnormal only because they are found at later than the expected ages, such as the various disabilities in information processing and the neurological "soft signs." What are the precise ages when, for example, not reading well or certain sorts of clumsiness become evidence for brain dysfunction? In other words, unlike the usual criteria for a syndrome, the characteristics of MBD are altered by maturation.

Definition Used in Current Research

The vagueness in the original definition of MBD and the failure of its proponents to differentiate the syndrome adequately from the normal seem to be responsible for confusion in both research and practice. The bewildered clinician, looking for some clarification as to what is being diagnosed as MBD by the experts, might expect enlightenment while perusing research papers. Our training has taught us that subjects under scientific study should be meticulously defined.

However, this quest will disappoint the clinician. In some cases the subjects are merely described as "hyperactive,"[8,9] as if this term were universally understood. In other studies the children described have been referred by other physicians with the diagnosis already made on criteria that are not revealed.[10,11] Some investigators simply say that the diagnosis was made in a previous study.[12,13] Connors' parent and teacher questionnaires[14] have been used as the means of diagnosis in many investigations although this technique may suffer from the major weakness of subjectivity. The mother or teacher is asked for general judgments as to whether the child is "restless or overactive," "excitable" etc or not. These global perceptions are given numerical scores and treated as if they were objective data.

This confusion as to who may be the subjects of these studies not only leaves ungratified our search for a definition of MBD but also makes the results of almost all these studies uninterpretable.

Criteria Used in Clinical Practice

If academicians and researchers have been so lacking in precision about the phenomena under study, we should hardly expect practitioners to be doing any better. Indeed, that seems to be the case.

Variations in reported frequencies of MBD or hyperactivity are probably a reflection of these multiple standards of diagnosis. Kenny et al[15] found that only a quarter of the children referred by practitioners to their diagnostic center for hyperactivity were actually overactive. Lambert et al[16] showed that the frequency of hyperactivity ranged from 1% to 13%, depending on who was defining it: parents, teachers, physicians, investigators, or some combination of these. Johnson and Prinz[17] concluded that hyperactivity is "in the eye of the beholder."

Sandoval et al[18] studied the criteria used for diagnosing hyperactivity in the Oakland, Calif, region and found that the prevailing practice was to rely primarily on behavioral descriptions from parents and little on observed behavior or other objective findings.

In considering the vague definitions and applications of the diagnostic terms, it is not surprising that there is a real problem in determining whether the elimination diet proposed by Feingold for "hyperactivity" has any therapeutic value.[19]

Consequences of Present Practice

The diagnostic confusion in the area of MBD and hyperactivity has led to

unfavorable consequences for children, their parents, and the professional persons who are trying to help them. The poor prognosis is evidence that current efforts are not working.

Children seem to be the ones to suffer the most, since even the best of present treatment of this ill-defined condition is far from satisfactory.[20] One major obstacle to suitable management is the uncertainty as to who has and who does not have the syndrome. One can only speculate as to the amount of iatrogenic pseudodisease[21] flourishing today as numerous neurologically intact children and their parents are informed that something is wrong with the child's brain. Once the label is applied to the child, the clinician must select from a variety of available therapeutic modalities: psychological, medical, educational, and dietary, none of which seems clearly superior to the others. The question about use of cerebral stimulants has been further clouded by the discovery that the behavioral changes induced by treatment (decreased activity and improved performance on cognitive tests), which were once thought to be specific and diagnostic of MBD, have also been demonstrated in normal children.[22] In a recent review of the literature Barclay[20] concluded that

> ... our current treatment approaches do not, as yet, appear to alter the prognosis of the disorder, as promising as they may be in the short-term manageability of these children.

This gloomy outlook is shared by authors of other recent reviews.[23-25]

Although children clearly are the ones most adversely affected by the diagnostic confusion over MBD, there are others who are deeply touched by it. As many clinicians know, parents are perplexed about the diagnosis and treatment of MBD or hyperactivity, since they are given conflicting advice by professional persons. However, the physicians, psychologists, and educators are laboring under the same disadvantage. To be a responsible clinician in the present setting is a formidable task. Finally, the research that should be showing us the way out of this quandry is largely trapped in the quagmire of diagnostic vagueness, as has been described above.

A WAY OUT OF CONFUSION

There seem to be only two ways out of the present diagnostic and therapeutic confusion. We must establish clear, objective criteria for these diagnoses or else we must discard them. If the terms are to be abandoned, some new diagnostic scheme must be developed to describe adequately the great variety of problems now grouped together under these labels.

In redefining hyperactivity as an attention deficit disorder,[4] the authors of the *DSM-III* seem to recognize the fact that for children having trouble adjusting to school, it is not the activity that is the main obstacle. However, although the *DSM-III* proposes six criteria for the syndrome between the ages of 8 and 10 years, it does not say how many of the criteria must be met, what is meant by such global diagnostic descriptions as "easily distracted" or "moves excessively during sleep," or exactly how the definition applies to other ages.

Those who believe that the terms are useful and who wish to retain them might look to the example of how Jones'[26] brought order out of diagnostic confusion over rheumatic fever in 1944. After his report it was no longer possible to say that any child with fever and joint pains had rheumatic fever. The physician was required to demonstrate two major or one major and two minor signs of the disease supported by evidence of recent streptococcal infection. All of these manifestations are objective findings (with the exception of the arthralgia, one of the minor ones) and none is based on hearsay evidence.

If MBD and hyperactivity were a coherent syndrome based on objective findings, such an approach would offer a real promise. However, there is a growing body of expert opinion from several disciplines that the syndrome is too diffuse and too subjective for such objective definition. These criticisms are based on several deficiencies noted in a variety of settings. In reviewing the literature on brain damage syndromes in childhood, Rutter[27] concluded that "the behavioral stereotype of the brain damaged child must be firmly rejected." Sandberg et al,[28] from a study of psychiatric clinic patients, decided that "there was no evidence for the validity of a broad concept of hyperkinetic syndrome." Shaffer and Greenhill[29] found that the diagnosis

> ... tells little about aetiology and does not permit generalizations to be made about clinical state. Its usefulness in predicting response to drug or other forms of treatment has yet to be demonstrated.

Schmitt[30] agreed, calling MBD a "myth." Saravia-Campos[31] believed it is an oversimplification and called for a return to the complexities of children as they really are. Ingram[32] said that MBD "is not a diagnosis; it is an escape from making one."

Our own research experience places us firmly in agreement with these views. In a recent study[33] of 60 children, referred to a pediatric neurologist by schools and physicians for problems in behavior and learning, data were collected on behavioral characteristics, cognitive or perceptual difficulties, and neurological soft signs. A reanalysis of those data showed that anywhere from 15% to 90% of this group could be given the diagnosis of MBD, depending on how the current diagnostic criteria were applied. One cannot fail to be impressed that for 75% of this referred population, the clinician's own interpretation of the existing diagnostic criteria could determine the diagnosis.

Since it appears unlikely that MBD and hyperactivity can be diagnosed on the basis of clear, objective criteria, it is our belief that the terms should be abandoned. Papers presented to our professional journals without meticulous description of the subjects being studied should be unconditionally rejected.

It is not sufficient, however, to deprecate the inadequacies of the current terminology of MBD and hyperactivity. Some clearer and more objective diagnostic scheme must be used in its place. We propose that problems in behavior and learning in children be diagnosed in terms of a neurobehavioral profile. Such a profile could consist in a summary of objective evi-

dence under six headings: (1) general physical status, including growth; (2) neurological status based on examination findings as to motor function, reflexes, coordination, including "soft signs," and sensation, including vision and hearing; (3) information-processing abilities; (4) maturation; both psychomotor, including speech, and cognitive; (5) temperament or behavioral style, in particular adaptability, attention span, and activity; and (6) psychosocial adjustment, including evidence of social cooperation, autonomy, aggressiveness, and withdrawal. Added to every neurobehavioral profile must be a description of the child's living situation, that is, the environmental input and interaction. If the child is viewed by parents or teachers as abnormal in any respect, the person complaining should be identified and the nature of the interactional difficulty described adequately. The profile would include strengths as well as disabilities and would always be subject to revision.

The neurobehavioral profile would replace vague general diagnoses with a summary of more objective data. Findings in one area, such as temperament or information processing, would not lead to unsupported conclusions in others, such as neurological status. The question of the importance of neurological soft signs[32-37] would be avoided by simply stating under the heading of neurological status what findings were present.

Three main purposes would thereby be served: (1) In clinical practice there would be a greater assurance that all pertinent factors would be considered in diagnosis and would be included in professional communications. Plans for therapy or special education based on detailed diagnostic profiles rather than stereotypic labels would have a greater chance of successfully meeting the needs of individual children. (2) In research there would be a more precise definition of subjects. Instead of calling a child simply "hyperactive," the researcher would be obliged not only to describe the child's activity but also to consider all the other pertinent aspects of the case. (3) In education it would be possible to encourage both teachers and students to think of children in their true complexity and avoid facile general diagnoses based on inadequate data.

It is likely that clinical syndromes based on more objective data from such a profile will emerge and will prove useful in clinical management of problems in behavior and learning in children. Such syndromes, however, would have the advantage of being clearly derived from more objective data and being unencumbered by vague terminology. It will take a great deal of effort to get to that point from where we are today, but our children deserve no less.

Elevated Meconium Lactase Activity

Its Use as a Screening Test for Cystic Fibrosis

Helen K. Berry, MA; Frank W. Kellogg, MD; Shirley R. Lichstein; Robert L. Ingberg, MD

• Screening of newborn infants could provide information needed to evaluate the effects of early treatment on the course and prognosis of cystic fibrosis (CF). Two procedures of screening meconium for CF were compared: increased albumin levels, detected by a commercial test strip; and increased lactase activity, detected by glucose production after incubation of meconium with lactose. Specimens positive by the lactase test were retested for albumin. Low-birth-weight infants accounted for more than half the positive test results with both procedures. Sweat chloride measurements were carried out only on infants whose meconium specimens had albumin concentration greater than 12 mg/g (wet weight), measured by radial immunodiffusion. Twelve infants with CF were identified through screening, six while testing 44,816 specimens by lactase activity test. Three additional infants with CF were missed because meconium specimens were negative to both tests.

(*Am J Dis Child* 134:930-934, 1980)

A number of studies have demonstrated raised levels of protein, predominantly of albumin, in meconium from infants with cystic fibrosis (CF).[1-3] On the basis of these studies, a reagent paper strip was developed that contains an indicator to detect increased albumin concentration (BMC Test Strip). This test is widely used in Western European countries.[4,5] In a one-year cooperative screening study in the United States, it was found that modifications of the test were needed before it could be recommended for mass screening. Problems centered around both false-positive and false-negative test results.[6]

For editorial comment, see p 925.

For the period of March 1975 through November 1976, the paper strip test was used to screen meconium specimens for increased albumin levels. Antonowicz et al[7] reported increased disaccharidase activity in meconium from infants with CF and suggested that measurement of lactase activity might be used as an alternative method for the detection of CF. We evaluated detection of raised lactase activity as a screening procedure in a period of from December 1976 through October 1979. During a period of from April 1976 through November 1976, both procedures were carried out, and we have compared results from them.

MATERIALS AND METHODS

Collection and Handling of Specimens

Six hospitals in the Cincinnati area participated in the screening program. The first meconium specimen available after the infant was transferred to the newborn nursery was collected, to avoid contamination with blood in the delivery room. Specimens were placed in clear plastic bags, 5.0 × 7.5 cm, labeled with name, sex, race, birth weight, and hospital identification, and then frozen. Approximately twice weekly, frozen meconium specimens were collected, thawed, and tested. Immediately afterward, specimens were refrozen and stored.

Testing by Paper Strip Test

A small amount of meconium was placed on the bottom of the test strip, which contained a dye (tetrabromophenolphthalein ethyl ester). The strip was inserted into a small glass tube that contained a few drops of water. Albumin was chromatographed in the dye-impregnated paper, and turned a distinctive blue in a positive test. All specimens that showed any color were designated as "screening positive," and quantitative measurements of albumin were carried out.

Detection of Lactase Activity

A small amount of meconium (approximately 10 to 20 mg) was placed in a 13 × 75-mm test tube. Then 0.5 mL of 3% lactose solution in 0.1M maleate buffer, at a pH of 5.4, was added, thoroughly mixed, and allowed to incubate for one hour at room temperature. At the end of the incubation period lactase activity was detected by the presence of glucose, demonstrated by a test stick (Clinstix, Ames Co, Elkhart, Ind). The minimum concentration of glucose required to give a positive test was 0.1 mg/mL. This would correspond to lactase

From the Institute for Developmental Research of the Children's Hospital Research Foundation and the Department of Pediatrics of Cincinnati College of Medicine, Cincinnati.

Reprint requests to Children's Hospital Research Foundation, Elland and Bethesda avenue, Cincinnati, OH 45229 (Ms Berry).

activity of 2 to 4 μmole/min/g of protein, if 10 to 20 mg of meconium was tested. All specimens with apparent lactase activity were tested for the presence of free glucose. Only occasional specimens showed free glucose prior to incubation with lactose. All specimens with tests positive for glucose were retested with the paper strip test for albumin. Quantitative albumin measurements were carried out on all specimens that were both lactase-test and glucose-test positive.

Quantitative Measurement of Albumin

Albumin was measured using commercially prepared radial immunodiffusion plates (M-Partigen Albumin, Behring Diagnostics, American Hoechst Corp, Somerville, NJ). An aliquot of meconium was weighed, combined with 9 v/v of water, and mixed thoroughly, followed by sonication. The supernatant after centrifugation was used for albumin determination. Albumin standards were prepared as directed by the manufacturer and used to construct a calibration curve. An aliquot of 5 μL of the supernatant was used. The assay range for albumin using these plates is 44 to 610 mg/dL, corresponding to a range of 4.4 to 61.0 mg/g of meconium (wet weight). Supernatants were diluted if necessary to extend the range upward. Values below 4.4 mg/g were estimated.

Proteolytic Activity by Gelatin Liquefaction

Beginning in 1977, specimens with albumin concentrations greater than 12 mg/g were tested for proteolytic activity as described by Westler and Neal.[8] Specimens from CF infants identified prior to 1977 were also taken from storage and tested if enough samples were left. Approximately 10 to 20 mg of meconium was suspended in 0.5 mL of tris chloride buffer, at a pH of 8.0, containing 0.05M calcium chloride solution and 0.02% sodium azide. An aliquot of 0.5 mL of 7.5% gelatin in tris buffer at a pH of 8.0 was added and the mixture thoroughly shaken. Incubation was carried out in a shaking water bath at 37 °C for one hour. The incubation mixtures were then refrigerated for several hours or overnight. Specimens containing less than 10 μg of trypsin per gram of meconium remained solid, whereas those with higher levels of proteolytic activity were liquefied.

RESULTS

The results of screening 20,490 specimens by paper strip test and 44,816 by lactase are given in Table 1. Comparison of the number of meconium specimens received with the number of infants born in a given year suggested that 98% of the infants were tested. Before screening for lactase was begun on a routine basis to replace the paper strip test, 100 specimens that were positive were retested for lactase activity. Twenty were positive on the lactase test. Specimens from five CF infants, identified by the paper strip test with positive sweat chloride tests, were among those positive on the lactase test. Then, approximately 8,000 specimens were tested by both procedures. Among 41 specimens positive on the paper strip test, 24 were also lactase-test positive. One infant with CF was identified during this period; the meconium was positive on both the paper strip and lactase tests. We believed these preliminary results justified the use of meconium lactase activity as a primary screening procedure.

There were relatively few positive tests using the paper strip test for primary screening, namely 138 or 0.67%. However, when lactase was used as the primary screening method, 3,957 (8.8%) of the specimens gave positive test results. Among the specimens positive on the lactase test, 98 gave positive test results with the paper strip test and were tested for albumin by immunodiffusion.

*Includes three infants with albumin levels less than 2 mg/g who were missed by meconium testing.
†A indicates gelatin solid after incubation, and no proteolytic activity with trypsin level less than 5 μg/g; B, no specimen left; C, gelatin liquefied; proteolytic activity present.
‡BMC Strip Test for albumin.
§Infant had meconium ileus.

The Figure shows albumin content of specimens that gave positive reactions with the paper strip test, either as the primary screening test or after the finding of increased lactase activity. Eighty percent of specimens positive on the paper strip test from low-birth-weight infants had albumin content less than 10 mg/g. Albumin content of greater than 12 mg/g (wet weight) was arbitrarily chosen as the cut-off point, above which sweat chloride measurements would be carried out. The number of specimens containing albumin concentrations of greater than 12 mg/g was similar with both screening procedures, 0.15% and 0.12% (Table 1), so that one infant in 666, compared with one in 833, was recalled for sweat chloride determinations.

Data on the relation of birth weight to test results are given in Table 2. The incidence of premature or small-for-date births was 2% in whites and 4% in blacks. In the initial phase of screening by paper strip test, low-birth-weight infants accounted for a high proportion of specimens with albumin content greater than 12 mg/g (55%). The incidence of low birth weight was slightly higher among infants with lactase-positive tests (3.9%) than in the total population tested (2.2%). Low-birth-weight infants accounted for 47% of the infants with specimens positive on lactase and albumin tests.

Table 3 gives data on family history, birth weight, sex, race, albumin content, proteolytic activity, and sweat chloride measurements of infants identified as having CF during the period of March 1975 to October 1979. Only infants born in participating hospitals were included in the study. Infants from high-risk families were included only if they would have been tested in the course of routine screening. In most instances, sweat chloride determinations were carried out at 4 to 6 weeks of age and again after 6 months of age. We were unaware of the family history in patients 1 and 3 prior to screening and learned of it only after reporting the positive results to the private physi-

cian. Two infants born in participating hospitals were tested for sweat chloride because of a positive family history, in spite of negative meconium tests (patients 6 and 13). Infant 12 had sweat chloride measurement because of recurring pneumonia during the first months of life. Only one infant had meconium ileus. All infants with CF were white and full-term. Sixteen percent of the infants tested were nonwhite. No black infants with CF were found among 10,077 whose specimens were tested. The incidence of CF among blacks is thought to be about one tenth that in whites.

Among babies tested first by paper strip test, the incidence of CF identified as a consequence of screening was six in 20,490 (1:3,400). Of those tested, 16,580 infants were white and full-term. As noted previously, one additional infant with CF (patient 6) was identified during this period because of a positive family history, for a combined total of seven infants with CF (1:2,400) among white, full-term infants tested. This brings the incidence close to the reported incidence in whites of 1:2,000.

Among babies tested first by lactase test, the incidence of CF identified through screening was six in 44,816 (1:7,500). Two infants with CF were not identified by meconium screening (patients 12 and 13), bringing the total number identified in this group to eight. These eight infants with CF were found while testing 37,134 white, full-term infants, for overall incidence during the period when lactase screening was carried out of 1:4,600, approximately half the anticipated incidence. It was expected that 15% to 25% of infants with CF would have normal pancreatic activity and would be missed by a screening test based on elevated albumin levels. It was, therefore, not surprising that three of 15 infants with CF were missed by meconium screening.

Meconium specimens from the three missed infants with CF had been recorded as negative on initial screening. They were taken from storage and retested. All were negative on second testing to paper strip, lactase, and quantitative measurement of albumin tests. Gelatin liquefaction as a test for proteolytic activity was applied to these three specimens, as well as a number of stored specimens positive on albumin test. As noted in Table 3, specimens from identified patients with CF had low or absent proteolytic activity, judged by their failure to liquefy gelatin, whereas specimens from the three infants with CF missed by screening had normal proteolytic activity. The majority of albumin test-positive specimens from premature and low-birth-weight infants readily liquefied gelatin in vitro, in spite of failure of digestion of albumin in vivo.

COMMENT

Attention has recently turned to the importance of early diagnosis for patients with CF. Shwachman et al noted the accumulation of evidence that early diagnosis and treatment affect morbidity and mortality from the disease.[9] Warwick estimated that up to 90% of undiagnosed patients with CF died during the first two years of life.[10] Lubin and Bonner found that of infants with CF diagnosed after 6 months of age, a larger proportion were below the 25th percentile for height and weight, than of those diagnosed before 6 months of age.[11] Palmer et al reported that early diagnosis and treatment was associated with a reduced number of hospital admissions, enhanced growth, and improved clinical condition.[12]

Screening for CF in infants could provide information needed to evaluate the effect of early treatment on the course and prognosis of the disease. The cost of screening might be recovered by recognition of CF in an infant prior to development of symptoms, thus avoiding costly hospitalizations for diagnosis. Screening for a genetic disease such as CF means that families recognize the presence of the disorder early and can make better decisions regarding future family planning.

Tests based on increased amounts of total protein or of individual proteins in meconium offer the best prospect as a screening procedure at present. The Cystic Fibrosis Foundation sponsored a collaborative study by four CF centers to evaluate the paper strip test as a means of detecting raised albumin levels in meconium.[6] Two additional centers, including the Cincinnati CF center, carried out independent studies at the same time and provided data. Among the problems cited in the report of the Collaborative Study were the presence of blood in specimens, failure to store specimens properly prior to testing or retesting, and a high incidence of false-positive test results among premature infants. They concluded the paper strip test, while useful in detecting albumin in meconium, was not sufficiently accurate alone to determine the indication for sweat chloride testing and recommended against its use in mass screening procedures until further data were obtained.

We believe meconium testing in our hands avoided some of the problems encountered in the Collaborative Study. All testing was carried out in a central laboratory. No attempt was made to judge the degree of positiveness of the paper strip test, but all samples that were not clearly negative were further tested for albumin content by quantitative immunodiffusion. The introduction of a quantitative test for albumin between paper strip testing and sweat chloride testing brought the ratio of confirmed patients with CF to albumin positive patients to slightly over 1:5. All paper strip test-positive specimens were also tested for the presence of blood. Relatively few were grossly contaminated because specimens were not collected in the delivery room. Our data are similar to those of the Collaborative Study in that low-birth-weight infants accounted for approximately half the meconium specimens with albumin content greater than 12 mg/g.

Follow-up of low-birth-weight infants presented some problems. Private physicians were routinely notified of infants having albumin over 12 mg/g and sweat chloride tests, free of charge, were recommended. Ninety-five percent of full-term infants had follow-up sweat chloride tests. Among low-birth-weight infants, only 45% had sweat chloride tests; 23% died prior to testing, and 32% were not referred for testing. This response

may reflect the fact that community physicians were less concerned about the likelihood of CF in their patients with low birth weights. Gelatin liquefaction as a test for proteolytic activity may be useful in reducing the number of infants called back for sweat chloride determinations.

Our preliminary testing of CF meconium specimens with positive paper strip tests confirmed the report by Antonowicz et al.[13] Our screening procedure differed from theirs only in that we used a longer incubation period at room temperature because of the large number of tests performed each day. Every specimen that showed any lactase activity was retested. There was a high proportion of positive lactase tests, relatively few of which showed increased levels of albumin. Those with low levels of albumin were readily eliminated by quantitative albumin measurements, and the incidence of infants who required sweat chloride determinations was similar to that found using the paper strip test for primary screening. There is considerable discrepancy between the reported incidence of CF, about 1:2000 in whites, and the final diagnosed incidence of 1:4,600 in white, full-term infants found after further study of lactase test-positive specimens. Prior to beginning the screening program, about 50% of the patients in the Cincinnati CF clinic were diagnosed by 18 months of age. No infants are known to have been missed during the period of lactase screening, other than the two described. Both came to our attention during the first 2 to 3 months of life. We are, however, concerned over the low yield of positive results using the lactase test as a primary screening method, and have stored the meconium specimens frozen in order that they may be retested if affected patients are found later. Seventy-five percent to 85% of the infants found to have CF during the period of March 1975 to October 1979 were identified by meconium screening. We do not know if the lower incidence of positively identified infants with CF during the past two years is a chance finding, or if affected infants were missed. It may be that no procedure based on meconium will prove ideal. Infants who have normal proteolytic activity, and presumably normal pancreatic function, will show negative reactions to any test based on increased levels of protein. The chief advantage of the lactase test is that the commercial test strip for detection of glucose is much cheaper than the commercial test strip for albumin. The chief disadvantage is the large number of positive test results, which must be studied further.

Until the basic genetic lesion is identified, it will be difficult to formulate a more specific test. Until a definitive test is available, it seems inadvisable to recommend mass newborn CF screening along the lines of current practice for phenylketonuria and other inborn errors of metabolism. On the other hand, if Warwick[10] is correct in his claim that there is a high mortality among undiagnosed patients with CF during the first two years of life, early diagnosis of even 75% of the affected infants seems sufficient to justify the effort.

This investigation was supported in part by the Ohio Unused Consumer Fund, the Ohio Department of Health, and National Institutes of Health grant HD05221.

BMC Test Meconium Strips used for the preliminary phase of testing were provided by Bio-Dynamics Division of Boehringer Mannheim Co, Indianapolis.

Personnel in the newborn nurseries of Bethesda Hospital, Christ Hospital, Cincinnati General Hospital, Good Samaritan Hospital, Jewish Hospital, and Mercy Hospital, Cincinnati, gave invaluable assistance in collecting and storing specimens. Local pediatricians referred patients for sweat chloride measurements. Anne Schaumberg, Jamie Campbell, Margaret Miller, and David Ringel carried out the screening tests.

Surgical Treatment of Gastroesophageal Reflux in Children

Results of Nissen's Fundoplication in 100 Children

Lucian L. Leape, MD, Max L. Ramenofsky, MD

• One hundred children underwent Nissen's fundoplication for complications of gastroesophageal reflux. Indications for fundoplication included refractory pneumonia, apneic spells, intractable vomiting, failure to thrive, esophagitis, esophageal stricture, and Sandifer's syndrome. Except for those with life-threatening complications, fundoplication was performed only in those who had failure with a strict medical antireflux regimen. Four patients were not helped by operation or had a recurrence of symptoms. Of these, three with refractory pneumonia were judged to be failures of selection since reflux was absent postoperatively. The fourth had massive reflux and recurrent vomiting. Eight other patients had radiologic evidence of reflux postoperatively. Six of these were asymptomatic and two had minor symptoms. There was one death and 11 postoperative complications.

(*Am J Dis Child* 134:935-938, 1980)

In the past few years, the diagnosis of gastroesophageal reflux (GER) has been made in children with increasing frequency. This increased recognition has resulted from the growing awareness that reflux is the cause of a varied group of significant disorders in children. It has also stemmed from more reliable detection of GER radiologically as improved techniques have been developed and disseminated.

A number of complications may result from GER. Vomiting, failure to thrive, recurrent pneumonia, and esophageal stricture have long been recognized. More recently, reflux has been incriminated as a cause of recurrent bronchitis, asthma, respiratory arrest, the sudden infant death syndrome,[1] Sandifer's syndrome, and protein-losing enteropathy.[2] Reflux may cause movement disorders that may be confused with seizures.[3] Symptomatic reflux esophagitis seems to be more common in childhood than previously suspected.

The majority of patients with GER do not have serious complications. Most infants suffer only from regurgitation, which responds readily to postural and dietary treatment. Some children with reflux are asymptomatic. Surgical treatment should be reserved for those patients with complications of GER that fail to respond to medical treatment or who have life-threatening complications.

Coincident with the increased frequency of diagnosis of reflux, Nissen's fundoplication has emerged as the operation of choice for patients in whom an antireflux procedure is necessary. This operation has consistently proved to have the highest rate of success and the fewest number of recurrences.[4]

At the Boston Floating Hospital, the number of patients seen annually with the diagnosis of GER has increased dramatically in the past five years, largely because of improvements in radiologic technique that have led to increased clinical awareness on the part of the referring physicians. Whereas a few years ago only a handful of patients were seen in whom the diagnosis was made, now more than 400 new cases of GER are seen annually. Few of these patients come to operation. Ninety percent are successfully treated medically.

In the five-year period ending in March 1979, a total of 100 children, aged 1 month to 13 years, underwent Nissen's fundoplication[5] at the Boston Floating Hospital for complications of GER. Ninety-six patients have been observed for a year or more. No failures or complications have appeared after six months in this group.

PATIENTS AND METHODS

Diagnosis

The diagnosis of GER was made by barium swallow roentgenogram in every patient. In experienced hands, GER is readily demonstrated radiologically. A diagnosis of GER was not made unless multiple episodes of reflux were seen under standardized conditions, as described by McCauley et al.[6] The patient is examined in the supine position without pressure on the abdomen or placing the head in a down position. An adequate amount of barium (equal to a normal feeding) must be given, and the patient must be relaxed. Reflux was not considered significant unless the patient's symptoms and other findings were consistent with this diagnosis.

From the Pediatric Surgical Service, Boston Floating Hospital, and the Department of Surgery, Tufts University School of Medicine, Boston.

Reprint requests to Boston Floating Hospital, 171 Harrison Ave, Boston, MA 02111 (Dr Leape).

In 17 patients with recurrent pneumonia and in 21 patients with apneic spells, 24-hour pH probe study was carried out. The probe was placed in the upper third of the esophagus to detect reflux to the upper part of the esophagus that could potentially reach the larynx and be aspirated. The frequency of episodes of reflux and its relationship to the patient's position and thickening of feedings were determined.

Manometric evaluation of esophageal function was not performed in these patients. Previous studies have shown that lower esophageal sphincter pressure is not more reliable as an indicator of significant reflux,[7] while it is more cumbersome and uncomfortable for the patient.

If esophagitis was suspected, the diagnosis was established by biopsy at esophagoscopy. All patients undergoing operation for esophagitis had esophagitis by visual examination through the esophagoscope, confirmed by histologic examination in each case.

Selection for Operation

Patients with symptomatic reflux were initially treated with a strict regimen of medical therapy. Often, prior treatment had been casual or minimal: "Prop him up for one-half hour after feedings," or "Put a little cereal in the formula." In persistently symptomatic cases, rigid adherence to the principles outlined by Carre 20 years ago are necessary.[8] All of these are important. First, there should be 24-hour positioning in the upright posture. This may be obtained by placing the infant in a seat at 60° or strapping him prone on a board at 45°. Second, all liquid feedings must be thickened. Effective thickening requires the addition of 15 mL of cereal to each 30 mL of formula. Third, the volume of feedings is decreased to prevent overdistention of the stomach. The frequency of feedings may need to be increased (eg, 90 mL every three hours instead of 120 mL every four hours). Patients whose sole symptom is vomiting will respond to this regimen 80% to 90% of the time. Except for patients with strictures and those with life-threatening apneic spells, surgical treatment was reserved for failures of medical therapy—patients who had persistent serious symptoms despite treatment.

Specific Indications for Surgical Treatment

Refractory Pneumonia (40 Patients).—In addition to demonstrated reflux, these patients had characteristic patterns of aspiration. The pneumonia was typically migratory, involving different segments of the lung at different times. Usually it was diffuse, but it was localized to a single lobe on occasion. Typically, the bacterial flora was not specific and the response to antibiotic therapy was sluggish or nonexistent. Two patterns of pneumonia have been observed—refractory and recurrent.

Patients with refractory reflux pneumonia were usually young infants who experienced a fairly severe pneumonia, often bilateral, which did not clear with medical treatment. In some cases, this was quite severe, necessitating intensive care and ventilatory assistance. Most of the young infants coming to operation in this series were in this category. These patients were failures of medical therapy of reflux. A few responded to continuous aspiration of the stomach with a nasogastric tube and parenteral nutrition, but promptly suffered a relapse when thickened feedings were begun.

The second pattern of recurrent pneumonia was more typical in the older child. These patients had frequent hospitalizations because of pneumonia, often three or four times in one year. Different lobes would be involved, and bacteriologic flora varied. Often, normal mouth organisms were found. Usually these patients also had increased tracheobronchial secretions—"rattles" and "congestion"—between episodes of pneumonia, frequent upper respiratory tract infections, otitis media, and chronic cough. Several had recurrent bronchitis, and two had recurrent severe attacks of asthma.

Since the vast majority of patients with GER do not experience pneumonia, it is assumed that these individuals had an additional abnormality, such as abnormal laryngeal protective reflexes that fail to prevent aspiration, particularly at night. An antireflux operation does not alter this second abnormality, but it does eliminate the possibility of gastric contents being delivered to the larynx.

Apneic Spells (16 Patients).—Respiratory arrest may be caused by GER.[1] Again, there are two patterns—minor and life-threatening. Minor apneic spells are characterized by frequent choking with apnea and cyanosis that responds to stimulation. The child is described by the mother as having difficulty getting his breath, not merely that he stops breathing from time to time. Patients have been selected for surgical treatment if such spells increased in frequency despite adequate medical treatment. These represented about one half of the patients who were operated on because of apnea.

Life-threatening apneic spells were seen in the other half. These patients suffered a major respiratory arrest that required resuscitation and hospitalization. In a typical spell, the child was noted to appear startled and silently struggling to breathe. He became agitated, reddened, and sometimes thrashed about; he then became pale, cyanotic, and limp. It is apparent to the observer that the patient is trying to breath and unable to do so. Many of these patients had one or more additional spells in the hospital where they were observed by medical personnel. Medical treatment was not tried in these patients because of an unacceptably high failure rate (there is at least one reported death from failure of positional and dietary therapy in a child with GER and a previous apneic spell).[9] In addition, parents and pediatricians found it unacceptable.

Most patients with apneic spells had no vomiting, and thus reflux was often not suspected as the cause. Further, most of them did not have pneumonia, so that hypoxia seems unlikely as the mechanism for apnea. As with pneumonia, we postulate that there is a second abnormality, again most likely immature laryngeal reflexes, but the evidence for this is only circumstantial. The evidence linking GER to the sudden infant death syndrome has been previously presented.[1,9] All of the patients in the current series were under 1 year of age, and those with life-threatening spells were all under 6 months of age.

Intractable Vomiting (13 Patients).—In general, these were older children. Half of them were mentally retarded, and vomit-

Results of Nissen's Fundoplication in 96 Patients

*None of these patients had radiologic recurrence.

ing was a major problem in their management. The others were children with multiple episodes of vomiting daily in whom medical treatment was unsuccessful. They had failed to "grow out of" reflux by 12 to 18 months. Several were older children with a lifelong history of vomiting in whom the diagnosis of reflux had not been made earlier.

Failure to Thrive (Six Patients).—These patients ranged in age from 3 months to 2 years. All failed to respond to medical therapy and exhibited progressive growth failure. All were below the fifth percentile in weight at the time of operation. All had a minimum of two months of medical therapy with lack of response before the decision to perform fundoplication was made. In several young patients, an additional trial of several weeks of in-hospital treatment with careful calorie counts was performed prior to surgery.

Esophagitis (Ten Patients).—These patients' symptoms manifested in several ways. Five had epigastric and substernal pain, three had dysphagia, two had bleeding, and one had perforation of an esophageal ulcer. They ranged in age from 4 months to 13 years. All (except the patient with the perforated ulcer) underwent a trial of medical therapy, including antacids, prior to selection for operation. All had the diagnosis confirmed by biopsy.

Stricture (Six Patients).—These were all older children, the youngest being 4 years of age. Two thirds of them were mentally retarded. None complained of pain. All of these first came to medical attention because of dysphagia. In one patient, psychotherapy had been recommended on the assumption that his dysphagia was emotional in origin. In addition to the stricture, reflux was demonstrated by barium study in each patient. Esophagitis at the level of the stricture was confirmed by biopsy.

Sandifer's Syndrome (Five Patients).—Spasmodic torticollis associated with hiatal hernia was described by Sutcliffe in 1969.[10] It is now recognized that GER, not hiatal hernia, is the causative factor. In our experience, it is not rare. All of our patients have had mild esophagitis proved by biopsy, and all those coming to operation were failures of medical therapy, including the use of antacids. Progressive facial deformity was the indication for surgical treatment.

RESULTS

Ninety-six patients have been observed since operation. Ninety-two (96%) have had a successful result. All patients have been followed up for at least one year. A follow-up upper gastrointestinal tract roentgenographic series was performed six weeks or more after fundoplication to detect possible recurrence of reflux.

Success or failure of fundoplication may be evaluated by a number of criteria: symptomatic, radiologic, manometric, pH, and histologic. Clearly, the important question is whether the patient has been relieved of his symptoms. This may not require complete elimination of reflux as determined radiologically. Consequently, the operation has been considered successful if the patient had no symptoms, even if there was a small amount of radiologic reflux postoperatively (six patients).

Failure to relieve symptoms by fundoplication may be the result of two possible causes: failure of the fundoplication to stop reflux, or failure of proper selection of the patient for the operation. That is, the operation has eliminated the reflux, but the symptoms persist. In these patients, GER was probably not the causative mechanism, or pathologic changes had progressed beyond reversibility and the operation was performed too late to be of value.

Patients with stricture represent a special group. Although elimination of reflux almost always leads to significant improvement, and is essential for successful treatment of the stricture, it is rarely sufficient by itself. All of our stricture patients needed esophageal dilations. The follow-up results are summarized in the Table.

Refractory Pneumonia

Thirty (75%) of the 40 patients have had no further episodes of pneumonia. In these patients, fundoplication resulted in an abrupt change in their patterns of persistent or recurrent pulmonary disease. Two had mild GER by follow-up barium study. Seven patients (18%) have had one subsequent episode of pneumonia, but are considered to have had successful results since the pattern of recurrent infections was broken and they subsequently have been well with relief of recurrent "congestion" and other symptoms. None of these patients had recurrent GER by roentgenographic examination.

In three patients (8%), fundoplication had no effect on their pulmonary disease. One patient, operated on at age 2 months because of severe nonresolving pneumonia, was operated on too late. He showed no improvement after fundoplication and eventually died of pulmonary insufficiency. The second was subsequently found to have a T-cell immunodeficiency and suffered recurrent pulmonary and cutaneous infections until he died three years later. In the third patient, there was no apparent reason for his recurrent episodes of pneumonia, but reflux was clearly not the primary mechanism. None of these three patients had radiologic evidence of recurrent reflux. Thus, they represent failures of selection.

Apneic Spells

None of the 16 patients operated on for apneic spells has had another spell. A minor degree of reflux was noted by follow-up barium study in one of these asymptomatic patients.

Intractable Vomiting

One of the 13 patients, the youngest in this group, experienced recurrence of vomiting approximately two months after fundoplication. Radiologic examination showed breakdown of the surgical repair with recurrent massive reflux. He was treated successfully with positional and dietary measures and has subsequently been free of symptoms without treatment for more than two years. He is considered a failure of fundoplication. The remaining 12 patients have had no further vomiting. Two asymptomatic patients demonstrated recurrent GER by barium roentgenogram two and three years after operation.

Failure to Thrive

There were no failures in this group of six patients. Reversal of the downward weight trend occurred following fundoplication in each patient, usually within two weeks after operation.

Esophagitis

One of ten patients has had minor symptoms with occasional fussiness,

which may be related to persistent reflux demonstrated by roentgenogram. His condition is considered to be improved, but not cured. The other nine patients are free of symptoms.

Stricture

All six patients have shown improvement, but all have required multiple dilations. One patient required segmental resection of the stricture after repeated dilations during a one-year period. He has subsequently been symptom-free for more than two years.

Sandifer's Syndrome

Facial deformity was corrected in all five patients. One patient has grade 1 persistent radiologic reflux with occasional head tilting.

Complications

There was one death. A 7-month-old boy was operated on for failure to thrive. Postoperatively, he experienced fulminant *Haemophilus influenza* pneumonia and died on the fourth postoperative day.

There have been seven operative complications (7%). Two of these were nonspecific for fundoplication—one wound dehiscence and one patient in whom a leak from a gastrostomy developed. Five were specifically related to the type of operative procedure. A leak at the suture line developed in two patients, requiring reoperation. One patient had a fundoplication that was too tight. This responded to a single dilation. Two patients had postoperative gastric stasis requiring prolonged intubation. Each responded to a short course of metoclopramide therapy.

Four patients had late complications (4%). Three of these were nonspecific—intestinal obstruction secondary to adhesions a month or more after operation. All required reoperation. The fourth patient experienced herniation of the fundoplication into the chest and required reoperation.

Several patients had less serious side effects or complications that required treatment. Five patients suffered from "gas bloat"—fullness and fussiness after feeding. These responded to treatment with simethicone with spontaneous disappearance of the symptom in four to six weeks. All of these were infants. Four other infants experienced diarrhea significant enough to delay discharge from the hospital. In two patients it was prolonged, but gradually subsided. The mechanism of diarrhea is unclear. There was no evidence of delayed gastric emptying to suggest vagal injury. It may be that inability to belch swallowed air led to intestinal hyperperistalsis. Evaluation of diarrhea is further compounded by the fact that the incidence in this series of patients was no greater than that seen in children of the same age hospitalized for other reasons and not operated on.

CONCLUSIONS

Nissen's fundoplication is a safe and effective antireflux procedure that can be expected to eliminate GER in all but a small percentage of those in whom it is used. Properly selected, patients with all of the recognized complications of reflux unresponsive to medical therapy will be relieved of their symptoms. Nevertheless, as with any major surgical operation, the potential for complications is such that the operation should be reserved for those who have life-threatening complications or those who are unresponsive to medical therapy.

Congenital Leukemoid Reaction Followed by Fatal Leukemia

A Case With Down's Syndrome

Hai-Peng Lin, MBBS, FRACP, MRCP, DCH; Hariharan Menaka, MBBS, MPathol; Kok-Hoo Lim, MBBS; Hoi-Sen Yong, PhD

• A serial clinical, hematologic, and cytogenetic study was done on a baby with Down's syndrome in whom a myeloid leukemoid reaction developed at birth that spontaneously regressed within a month only to relapse two years later to an acute undifferentiated stem cell leukemia. He died 1½ months after onset. The unresolved controversy of the diagnosis of the congenital leukemia-like state is discussed. The importance of following up such patients with apparent remission of their congenital leukemia-like disorder is emphasized.

(*Am J Dis Child* 134:939-941, 1980)

The estimated incidence of congenital leukemia in Down's syndrome is three to 61 times that of the general population.[1,2] The high rate of spontaneous remission seen in such cases has led to the still unresolved controversy of whether the phenomenon is a true leukemia or a transient leukemoid reaction, the result of ineffective regulation of granulopoiesis.[3,4] The remission is permanent in most instances but rarely it is terminated by leukemic relapse five to 30 months later.[5,6] This case report illustrates this unusual course and highlights the controversy over the diagnosis of congenital leukemia in Down's syndrome.

REPORT OF A CASE

This boy was born on April 13, 1977, at the University Hospital, Kuala Lumpur, Malaysia, after an uncomplicated term pregnancy. The mother was 41 years old and the father 46 years old. He had one sister, aged 7 years, who is well.

The birth weight was 2,968 g and there were obvious stigmata of Down's syndrome at birth. The baby was well but routine examination showed an enlarged liver, palpable 3 cm below the right costal margin. The spleen and the lymph nodes were not palpable and there was no pallor, petechiae, or skin nodules. Results of fundi examination were normal.

Laboratory investigations done on the first few days of life included the following values: hemoglobin, 15.3/dL; platelet, 44,000/cu mm; total WBCs, 24,200/cu mm; myeloblasts, 13%; neutrophils, 76%; lymphocytes, 8%; monocytes, 3%; and reticulocytes, 5%. Both mother and the baby were blood group A, Rh-positive. Direct Coomb's test was negative, glucose-6-phosphate dehydrogenase level (G6PD) was normal, and urine tests were negative for urobilinogen and bilirubin. Karyotyping showed 47 XY, trisomy 21. The bone marrow examination at day 4 showed a very cellular marrow with a shift of granulopoiesis to the left. There were about 15% myeloblasts that were negative for PAS and peroxidase. The leukocyte alkaline phosphatase score was 216. Megakaryocytes were scarce. In view of the good clinical state, the lack of pallor and the small percentage of blastforms in the bone marrow, a diagnosis of myeloid leukemoid reaction was made. Serology titers for congenital toxoplasmosis, rubella, cytomegalovirus, herpes simplex, and syphilis were not significant and blood culture was negative.

During a period of one month, the liver size and the platelet count spontaneously returned to normal, and the blastforms disappeared from the peripheral blood. Results of repeated bone marrow examination were normal.

The child was followed up regularly and remained relatively well with good physical growth but mild developmental retardation. At the age of 2 years, he was noted to be very pale with generalized purpura. The liver was enlarged 4 cm and the spleen was enlarged 4 cm below the costal margin. Laboratory values were as follows: hemoglobin, 5.2 g/dL; platelets, 11,000/cu mm; WBCs, 23,000/cu mm; blastforms, 10%; neutrophils, 16%; lymphocytes, 74%; and reticulocytes, 0.1%. The bone marrow was

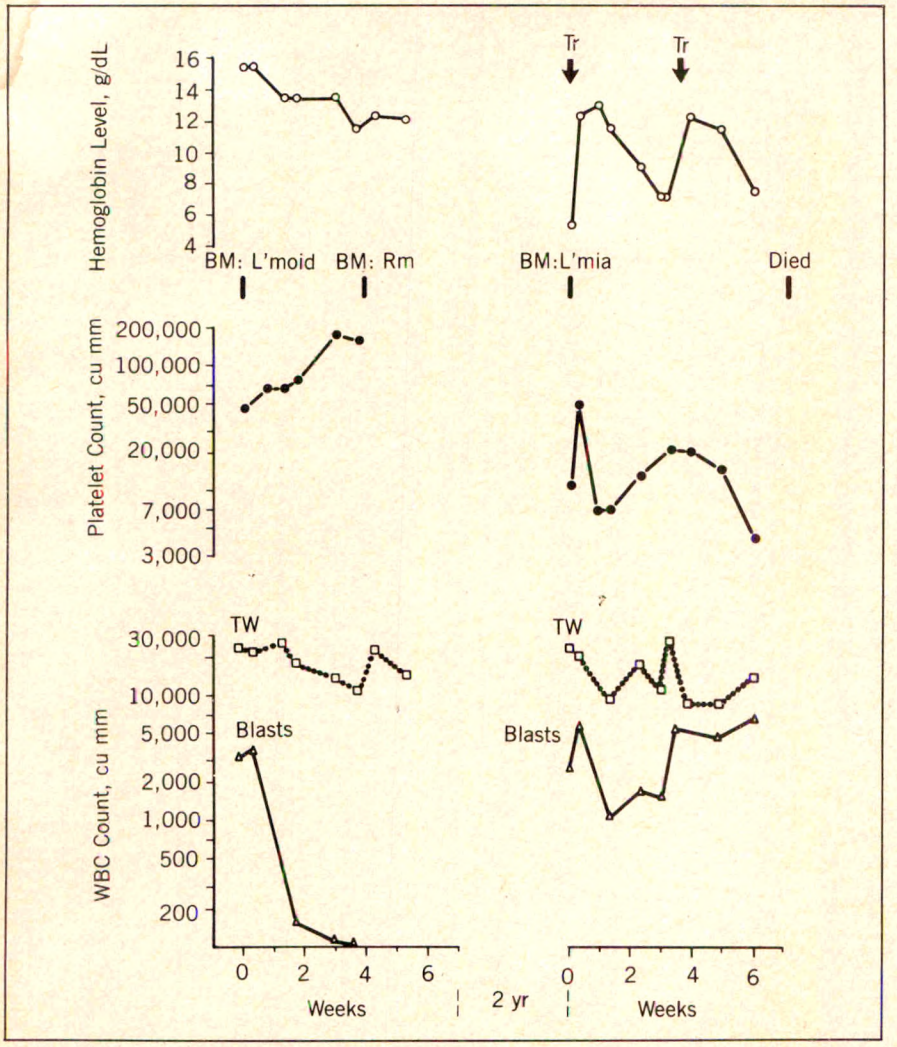

Fig 1.—Serial blood cell counts on child with Down's syndrome: BM indicates bone marrow; Tr, packed-cell transfusion; L'moid, myeloid leukemoid reaction; Rm, remission; L'mia, acute undifferentiated leukemia; and TW: total WBC count.

hypercellular with predominantly myeloid elements but reduced erythropoiesis and thrombopoiesis. The differential cell count of the WBCs was as follows: 56% blastforms that were occasionally positive for PAS and peroxidase; 28% promyelocytes, myelocytes, and metamyelocytes; and 16% lymphocytes. There were a few erythroblasts. The diagnosis was that of an undifferentiated stem cell leukemia. Repeated chromosome culture showed 47 karyotype with trisomy 21 in the majority of the cells but in addition, occasional cell lines showed 48 or 49 chromosomes. However, the nature of the additional chromosomes was uncertain.

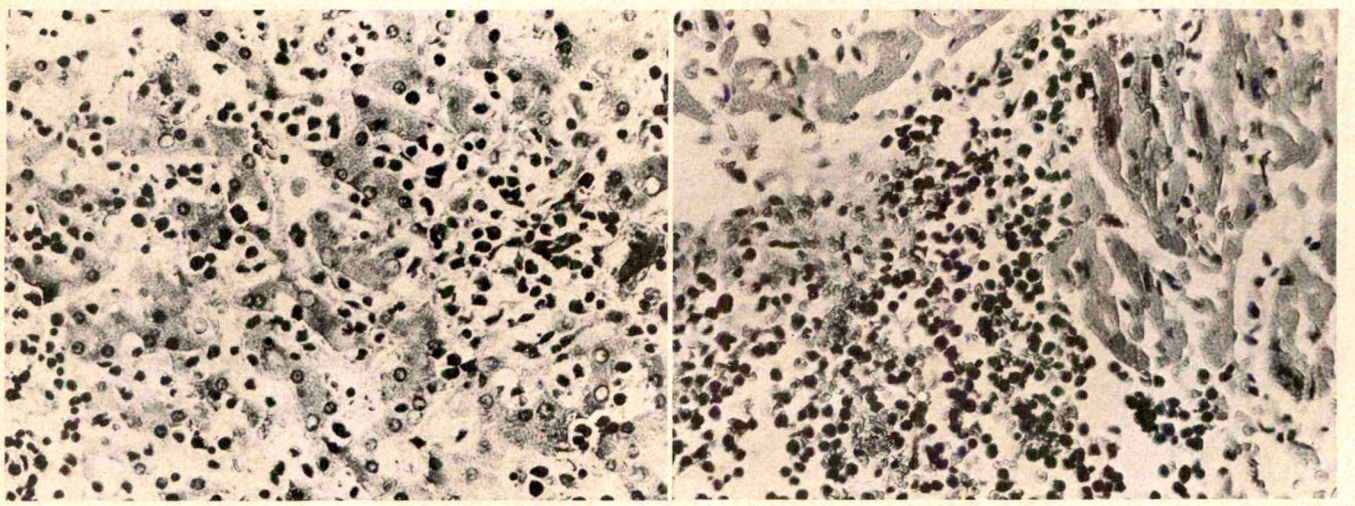
Treatment was withheld with the parents' consent. The patient's condition had a progressively downhill course leading to his death 1½ months after the leukemia was diagnosed (Fig 1).

Autopsy showed terminal bronchopneumonia and widespread mononuclear cell infiltration of the liver, heart, kidney, and lymph nodes in the mediastinum and abdomen (Fig 2). The brain and the gut were normal.

COMMENT

The controversy regarding the nature of the abnormal myelopoiesis found in newborn infants with Down's syndrome remains unresolved. It may represent a transient myeloid leukemoid reaction, the result of ineffective regulation of granulopoiesis masquerading as congenital leukemia.[3,7,8] This view is mainly based on the high spontaneous remission rate observed in such patients, the majority of whom achieved permanent re-

Fig 2.—Photomicrograph of sections of liver (left) and heart (right) at autopsy showing infiltration by mononuclear cells (hematoxylin-eosin, original magnification ×400).



ission within one to five months from birth. Many who died years later of unrelated disorders were found on autopsy to be free of leukemia.[3,4,9] Such behavior is atypical of true leukemia. The existence of congenital leukemia was questioned on the basis that it may be a reaction to such stimuli as sepsis or blood group incompatibilities that were found in some earlier reports.[7,10] In addition to the occurrence of leukemoid reaction, there were reports of other less common myeloproliferative disorders occurring among newborns with Down's syndrome, such as polycythemia and thrombocytosis.[11,12] To further support this hypothesis were the observations that there were ultrastructural, enzymatic, and functional differences between the myeloblasts of patients with Down's syndrome as opposed to those without this syndrome.[13,14]

It is also possible that the abnormal granulopoiesis represents true leukemia in that the usual clinical and laboratory criteria for leukemia are satisfied—pallor, hepatosplenomegaly, purpura, skin nodules, and blastforms in the peripheral blood and bone marrow. It was suggested that the high rate of spontaneous remission was not incompatible with the diagnosis but should instead stimulate research as to why patients with Down's syndrome should recover from leukemia.[4] Moreover, there were some patients who died of congenital leukemia without achieving a remission.[6] Although permanent remission is the rule, there are occasional reports of patients with Down's syndrome who went into spontaneous remission initially only to die five to 30 months later of frank leukemia.[5,6] This unusual clinical course was followed in our patient. The transient congenital blood disorder was probably due to a myeloid leukemoid reaction as the baby was well, the liver was only slightly enlarged, and there were only about 15% blastforms in the bone marrow, although the thrombocytopenia was moderately severe. However, obvious stimuli to this "reaction" could not be identified as there was no blood group incompatibility, G6PD deficiency, hemolysis, intrauterine, or neonatal sepsis. The fact that a true leukemia developed after two years illustrates the importance of close follow-up of such cases for as long as possible.

The importance of the 48 or 49 chromosomes in occasional cell lines seen on chromosomal cultures of peripheral blood during the leukemic phase in this patient is unknown. In a similar patient with Down's syndrome with trisomy 21, where serial cytogenetic studies were done, it was found that with exacerbation of the leukemia the cell line with 48 chromosomes (the additional chromosome being in the six to 12 group) became the major line in the bone marrow.[5] Unfortunately, in our patient, the identity of the additional chromosomes could not be ascertained.

Immunologic Maturation in an Infant Born to a Mother With Agammaglobulinemia

Roger H. Kobayashi, MD; Charles J. Hyman, MD; E. Richard Stiehm, MD

• **An infant born to a mother with agammaglobulinemia was followed up since birth to study immunologic maturation uninfluenced by circulating maternal antibodies. Immunoglobulin levels remained low and antibodies to immunizing antigens appeared late. These observations, together with findings in two other reported infants born to agammaglobulinemic mothers, suggest that transplacental maternal antibodies play little or no role in modulating newborn IgG production and that the delay in achieving normal levels of IgG are probably due to the immaturity of newborn B lymphocytes.**

(*Am J Dis Child* 134:942-944, 1980)

Most term neonates are born with adult levels of IgG acquired transplacentally from the mother. These provide temporary protection against many infectious agents until the infant can synthesize his own antibodies.[1,2] The exception is the infant born to a mother with agammaglobulinemia. We recently cared for such a child and because of his excellent clinical condition, a responsible mother, the possibility of suppressing endogenous IgG synthesis, and the favorable outcome in three similarly untreated infants,[3-5] we elected not to give the child γ-globulin injections. This also provided an opportunity to study an infant's immunologic maturation uninfluenced by maternal or exogenous γ-globulin.

REPORT OF A CASE

The child's mother was a 22-year-old woman in whom upper respiratory tract infections developed during the third trimester of each of her two pregnancies (at ages 19 and 22 years, respectively). Her history showed no serious infections, early infantile deaths, arthritis, or consanguinity. During her second pregnancy, results of protein electrophoresis obtained during the third trimester revealed an absent γ-globulin spike; however, immunoglobulin levels were not measured. Although the delivery at a community hospital was uneventful, she continued to cough persistently. She was given γ-globulin injections, 5 mL every two weeks. Her immunoglobulin levels at the time of delivery were 98 mg/dL of IgG, 14 mg/dL of IgM, and 12 mg/dL of IgA. She was referred nine days postpartum to the UCLA Medical Center, Los Angeles, at which time her immunoglobulin levels were as follows: IgG, 164 mg/dL (normal, 1,158 ± 305 mg/dL); IgM, 25 mg/dL (normal, 99 ± 27 mg/dL); and IgA, 2 mg/dL (normal, 200 ± 61 mg/dL). Polio (viral neutralization) and tetanus titers were negative. T-cell enumeration (E rosettes) was 75% (normal range, 65% ± 10%) and B-cell enumeration (surface membrane Ig) was 3% (normal range, 15% ± 10%).

Results of studies to assess suppressor T cells and in vitro immunoglobulin synthesis indicated that her hypogammaglobulinemia was due to an intrinsic B-cell defect. Addition of normal T cells did not result in production of immunoglobulin by her B cells. Her T cells did not suppress normal B-cell in vitro immunoglobulin synthesis, nor were suppressor lymphokines produced. The methods are described elsewhere.[6]

The results of a physical examination were unremarkable, except for postnasal discharge and scarcity of lymph tissue. Sinus roentgenograms showed pansinusitis, and the chest films suggested a retrocardiac infiltrate. Her condition responded well to γ-globulin injections (0.7 mL/kg/mo) and administration of oral penicillin and nasal decongestants. Subsequently, she has been free of symptoms during ten months of follow-up, although her immunoglobulin levels have remained low. Repeated roentgenograms have been normal.

The propositus, a boy, was born on May 16, 1978, and weighed 2,640 g at birth. There were no postnatal difficulties. Measurement of immunoglobulin levels at birth revealed the following: IgG, 90 mg/dL; IgM, 24 mg/dL; and IgA, not detected. He was referred to UCLA at 9 days of age, along with his mother, for an immunologic evaluation. Results of these studies are given in the Table and the Figure. The immunoglobulin levels at that time were as follows: IgG, 100 mg/dL (normal, 1,031 ± 200 mg/dL); IgM, 6 mg/dL (normal, 11 ± 5 mg/dL); IgA, 2 mg/dL (normal, 2 ± 2 mg/dL); T cells, 62% (normal range, 65% ± 10%); and B cells, 16% (normal range, 15% ± 10%). In vitro lymphocyte stimulation with phytohemagglutinin was normal.

The child was robust and thrived. At 2

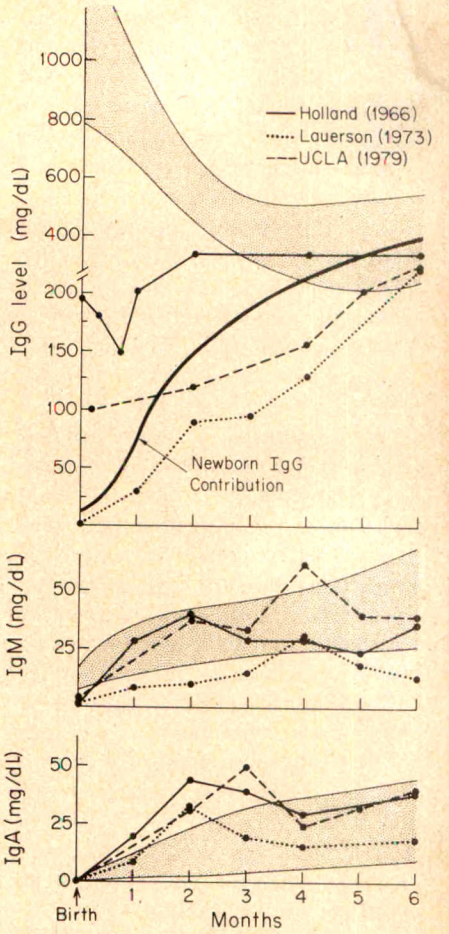
months of age he weighed 5.2 kg, and at 7 months of age he weighed 8.0 kg. Except for one mild bout of rhinitis at age 2 months, he was not ill. He was not given γ-globulin injections, but formula feedings were supplemented with donor breast milk until he was 5 months of age. Diphtheria-pertussis-tetanus and killed-polio vaccines were given at 2, 4, and 6 months of age (Table). Immunoglobulin levels, isohemagglutinin titers, and antibody response to poliovirus and tetanus antigen were followed serially. A Schick test was negative at 7 months of age, indicating the presence of antidiphtheria antibody.

An older female sibling, now 2 years old, also born in a small community hospital, had group B streptococcal sepsis at 3 days of age that required hospitalization and therapy for two weeks. Since it was not known at that time that the mother was hypogammaglobulinemic, no immunological studies were carried out. The child has subsequently done well. Immunoglobulin levels obtained on this child (age 2 years) at the time of the evaluation of the mother and propositus were as follows: IgG, 740 mg/dL (normal, 762 ± 209 mg/dL); IgM, 45 mg/dL (normal, 58 ± 23 mg/dL); and IgA, 40 mg/dL (normal 50 ± 23 mg/dL).

COMMENT

Immunoglobulin synthesis in the neonate is slow to develop. Contributing to this delay are the immaturity of the neonatal cells involved in immunoglobulin production, the possible inhibition from circulating maternal immunoglobulins, and the protected environment present in most newborns, which diminishes exogenous antigen contact.[7-10] Thus, endogenous IgG levels in infants of normal mothers are negligible at birth, climb to a level of 200 mg/dL at 2 months of age, and continue to rise, so that by age 1 year a value of 800 mg/dL is reached. It has been known for a long time that circulating maternal antibodies may interfere with selective antibody response in the infant. This interference is limited since newborns can respond to certain vaccines.[2,11,12] If a suppressive effect exists, then in the absence of circulating maternal antibodies one would expect infants from mothers with agammaglobulinemia to synthesize IgG earlier and thus achieve levels of endogenous IgG at comparable ages higher than those of children of normal mothers. In addition, the lack of maternal antibody interference should expose the child to increased antigenic stimulation, further providing impetus for increased antibody production. However, this expected increase in IgG level was not seen in our patient. Rather, his IgG level was slightly lower than the endogenous IgG levels seen in normal newborns during the first 8 months of life (Figure). His IgM and IgA levels were not significantly increased over normal values, either.

Similar observations have been made in two other children born to agammaglobulinemic mothers.[4,5] Indeed, the infant reported by Laursen and Christensen[5] had IgG levels below 100 mg/dL for the first 3 months of age, which by 5 months of age rose to a mere 150 mg/dL (Figure). In an early report, Bridges et al[3] noted that γ-globulin levels determined by electrophoresis were undetectable in a child from a mother with agammaglobulinemia until 42 days of life, and positive titers to *Salmonella* sp did not appear until 67 days of life, despite



IgG, IgM, and IgA levels in three infants born to agammaglobulinemic mothers (IgG values include small contribution from mother). Shaded areas represent Ig levels for normal infants (± 1 SD) and dark, solid line represents endogenous IgG from normal newborns.[1]

exogenous stimulation from bacterial colonization and repeated typhoid vaccinations. A second child born to this same mother did not produce detectable levels of γ-globulin until 28 days of life.[13] These observations and the response in our child suggest that transplacental maternal antibodies only play a minor role, if any, in modulating total IgG production in the neonate.

Bridges et al[3] attributed this lack of immunoglobulin and antibody formation to the absence of plasma cells. Indeed, plasma cells did not become abundant in these and normal infants until several months later. Recent studies to evaluate B- and T-cell interaction further elucidated the possible mechanisms for delayed IgG synthesis.[14,15] Hayward and Lawton[14] ob-

served that newborns have normal numbers of B cells of all classes, but that differentiation in vitro into plasma cells that synthesize IgG is impaired even when adult helper T cells are used. Moreover, newborn T cells suppress both adult and newborn B-cell differentiation and also do not help B-cell differentiation as effectively as do adult T cells. Thus, it seems that the limited IgG synthesis is both an intrinsic B-cell deficit and a T-cell regulatory phenomenon uninfluenced by exogenous IgG.

Could maternal T suppressor cells play a role in the less than expected IgG production in our child? Waldmann et al[16,17] suggested that some patients with common variable hypogammaglobulinemia have excess suppressor T cells, which are responsible for their diminished immunoglobulin production. Thus, if the mother had excess T-cell suppression causing her hypogammaglobulinemia, it is conceivable that these cells or a product of these cells could cross transplacentally and inhibit newborn B-cell differentiation. However, in vitro assessment of the mother did not demonstrate excess T-cell suppression or suppressor substances. Furthermore, this should be a short-lived effect. Therefore, it is unlikely that these factors were responsible for the slow IgG rise in our child. Whether maternal T-cell suppression played a role in the previously reported cases is not known, since these techniques were unavailable at that time.

Specific antibody response to polio and to tetanus vaccine were assessed in our child. A positive titer (polio $> 1:4$; tetanus $> 1:8$) was finally seen after three vaccinations. In normal infants, an antibody response develops in 80% after the first polio immunization (killed vaccine)[18] and in 85% to 92% a response develops after the second.[18,19] Immunization with tetanus toxoid is even more effective, ie, a 98% response rate after the first vaccination and nearly 100% conversion after the second vaccination.[20] The results given in the Table indicate that our infant's response was delayed. This is somewhat surprising, since he would be expected to respond at least as well as normal infants, and perhaps even better since maternal antibody interference was not a factor. Donor breast milk was given to supplement formula feedings to take advantage of possible anti-infective properties[21] contained therein. Although immunoglobulins contained in breast milk are not absorbed from the gut to an appreciable extent, thus not influencing the level of the infant's immunoglobulin, it is conceivable that the breast milk may have reduced colonization of coliform bacteria. This could have the effect of lessening antigenic stimulation and reducing immunoglobulin production.

It is interesting to note that the older sibling of our patient had neonatal group B streptococcal sepsis. The mother was presumably agammaglobulinemic at that time and was unable to make antibodies. Thus, the older child could have been vulnerable to this organism since Baker and associates[22-24] have suggested that maternal antigroup B streptococcal antibodies will protect the infant against this organism. Following this episode, the older child did not have further problems with infection.

In summary, despite low levels of IgG, our patient did well clinically and had only one mild respiratory infection in the first year. No special precautions were taken other than to supplement formula feedings with donor breast milk for five months. Other infants born to agammaglobulinemic mothers have not been unduly susceptible to infections.[3-5]

This investigation was supported in part by National Foundation grant 6-19 and US Public Health grants AI-07008 and HD-09800.

Studies to assess suppressor T cells and in vitro immunoglobulin synthesis were performed by Andrew Saxon, MD, of the Department of Medicine, UCLA School of Medicine, Los Angeles.

RBC Values in Low-Birth-Weight Infants During the First Seven Weeks of Life

James A. Stockman III, MD, Frank A. Oski, MD

• **Hemoglobin, RBC mean corpuscular volume (MCV), and other RBC indices were studied in a group of 40 infants, each with a birth weight of less than 1,500 g. Results indicated that the hemoglobin level fell from 18.2 ± 2.7 g/dL at birth to a low of 9.5 ± 1.5 g/dL at 6 weeks of age. During this time, the MCV declined from 115 ± 5 fentoliters (fL) to 97 ± 5 fL and did not again rise as the hemoglobin stabilized. Although the decline in MCV may simply reflect an aging RBC population, these data raise the possibility that RBC size may in part be determined by postnatal factors independent of time from conception.**

(*Am J Dis Child* 134:945-946, 1980)

The determination of RBC mean corpuscular volume (MCV) in the newborn has been found to be useful in the diagnosis of several disorders, including intrauterine blood loss and α thalassemia syndromes.[1,2] Normal data for the MCV now exist for full-term infants as well as for older children.[3,4] This report provides data on the developmental changes in RBC indices in a group of infants who were born prematurely.

STUDY METHODS

Hemoglobin, RBC count, MCV, mean corpuscular hemoglobin (MCHb), and mean corpuscular hemoglobin content (MCHbC) determinations were performed by electronic counting.[5] Forty infants, each with a birth weight of less than 1,500 g (mean birth weight, 1,290 g; range, 880 to 1,495 g), were observed, with weekly determinations of RBC indices being made through the seventh week of life. All infants were of appropriate birth weight for their gestational age. The infants had no major medical or surgical complications requiring supportive care. All infants were being fed orally with commercially prepared formulas containing 15 IU α-tocopherol without added iron. Serum α-tocopherol levels, measured biweekly by the method of Quaife et al,[6] demonstrated no evidence of vitamin E deficiency. No infant had been transfused. Infants were excluded from the study if the cumulative blood losses from blood drawing exceeded 5% of the infant's estimated blood volume of 90 mL/kg. Blood for the study was obtained by the capillary technique after careful warming of the sampling site. Informed consent was obtained for this study.

RESULTS

The changes in values for hemoglobin, MCV, MCHb, MCHbC, and RBCs may be seen in the Table and in the Figure. The MCV declined from a value of 115 ± 5 fentoliters (fL) to 95 ± 5 fL by 7 weeks of age. Although it is known that the MCV obtained on the first day of life is inversely related to gestational age,[7] the decline in MCV over the first few weeks of life in this study group far exceeded that which could be accounted for by increasing age as a function of time from conception. Similar changes occurred in the MCHb while the MCHbC was relatively constant from the time of birth. The electronic counting equipment utilized for this study determined hemoglobin, MCV, and RBC counts directly while deriving values for the MCHb and MCHbC. There is no reason, however, to assume inaccuracies in the derivation of the MCHb and MCHbC.

COMMENT

The developmental changes that occur in the RBC indices of premature infants are characterized in the first few weeks of life by falling hemoglobin and RBC counts as well as by a progressive decline in the MCV and MCHb. The fall in MCV is more rapid than that observed in full-term infants.[8] Unlike the changes that

	RBC Values*

occur in fetal hemoglobin synthesis,[9] the changes in the RBC indices do not appear to be related to postconceptional age but rather to the extrauterine age.

The etiology of the decline in the MCV of these infants is not known. It is extremely unlikely that iron deficiency is in any way related to the changes that occur in the MCV during the first two months of life. Lundström et al observed no differences in the hemoglobin or MCV values at 8 weeks of age when comparing a group of infants who were born prematurely and whose diets were supplemented with 2 mg/kg/day of elemental iron with those who received no supplemental iron.[10] It should be noted that the MCV values obtained at 4 and at 7 to 8 weeks of age by the latter investigators are virtually identical to those from this study.

The decline in the MCV after birth may be the result of an aging RBC population in the face of the shortened RBC survival and the bone marrow erythroid hypoplasia that are common at this age. Normally, however, as a population of RBCs ages, there is a concomitant rise in the MCHbC of these cells, which was not observed in our series of prematurely born infants.

In addition, when in this group of 7-week-old infants the hemoglobin level no longer was observed to be falling, the MCV continued to decline. These findings suggest that the changes that occur in RBC size may represent an interesting adaptation to extrauterine life.

Women Who Abuse Their Children

Implications for Pediatric Practice

Barbara Rosen, PhD, Martin T. Stein, MD

• Parents who abuse their children may not accept traditional therapy but may be influenced by the child's primary care physician. A comparative study of abusive and nonabusive mothers showed abusers to have lower self-concept and higher self-concept incongruence and inconsistency than nonabusers. They were also found to value authority over others more, and conformity and benevolence less, than nonabusers. Practically applied, the data lead the pediatrician to an educative and supportive role in which he or she may enhance self-esteem and lower unrealistic expectations in the course of treating the child. In addition, there seems to be a need to develop access to support groups, day care, and other avenues for the mother's personal growth. This may be done either within a pediatric practice or through liaison with community resources.

(*Am J Dis Child* 134:947-950, 1980)

In recent years, several studies have described the psychodynamic and demographic characteristics of child abusive individuals.[1-5] Although the data probably remain skewed by underreporting from the private sector, salient demographic factors include a preponderance of poor, female-headed households with an above-average number of children and a high rate of developmental vulnerability, such as prematurity, physical disability, or intellectual deficit in the child.[3,6,7] Abuse occurs among all socioeconomic and psychodiagnostic groups. One salient interpersonal factor, however, is that abusive parents generally maintain unrealistically high levels of expectation from their children, repeating the intense demand for and incapacity to nurture that they experienced in their own original families.[4] Their personalities are often characterized by a dependency and impulsivity that results in a role-reversed interaction with the child. The child is perceived as the unsatisfying and unsatisfiable parent of their own early lives.[1,4]

Although early identification of high-risk parents and referral to various counseling resources may represent a substantial positive outcome of such findings, less has been written on their practical application for the primary care physician in the office setting. Pediatricians must consider both the prevention of child abuse and the amelioration of the abusive impulse in the parents as an important aspect of their professional responsibility. Helfer[8] has indicated that the pediatrician "must see this responsibility as an involvement with the total family unit and not find himself caught up in the complex situation of alienating the parents in his attempt to help the child. He must make use of every talent, both his own and others, available to him, constantly keeping in mind his role as the *family* physician." Open and effective communication between physicians and parents is essential if such individuals are to trust their pediatricians enough to acknowledge the problem and accept and integrate their suggestions constructively. Often parental acknowledgment of the problem of the child abuse and neglect can come only after considerable groundwork has been laid, including successful parenting experiences based on the physician's advice. This study represents an attempt to translate objective psychological data, which confirm clinical impressions of abusive women, into practical application in the primary care pediatric setting.

METHOD

The present article is based on a comparative study of 30 abusive and 30 nonabusive mothers. The experimental group consisted of women participating in group and individual counseling at the Family Stress Center, a prevention and treatment center in Chula Vista, Calif, that accepts referrals from social service, health, and law enforcement agencies. Criteria for selection were admission of physical abuse, ranging from mild to severe nonaccidental trauma and, to minimize the effects of therapy, less than two months of participation in the program. Severity of abuse and possible presence of other abusers in the household were not assessed. Questionnaires were distributed to all abusive women entering small therapy groups. All participants returned the questionnaires anonymously at the next meeting. The group results were shared and discussed at subsequent sessions.

The control group was comprised of mothers attending the Pediatric Primary Care Center at University Hospital, San Diego. They were asked to complete the study questionnaires by the researcher during the waiting period for routine examination of children considered by the primary pediatrician to be free of suspected abuse, neglect, or major physical illness. They were told that the results would not be available unless specifically requested. Informed consent was obtained in both groups. An acknowledged limitation of the study is that the experimental group may have been more introspective and psychotherapeutically oriented than the control group.

All subjects were administered the following: a personal data sheet requesting relevant demographic information; Weedman's Self-Concept Incongruence Scale (SCIS), a 16-scale semantic differential test designed to assess positive self-concept, self-concept incongruence, and self-concept inconsistency[9]; Gordon's Survey of Interpersonal Values (SIV), a 6-scale forced-choice questionnaire that measures the most salient values involved in a person's relationships with others.[10] Both instruments have been validated with subjects demographically similar to those in the present study.

Subjects completing the SCIS are asked to rate themselves on two sets of 6-point scales, one entitled "The Way I See Myself" and the other "The Way I Would Like to Be." Scaled items included adjectives, such as friendly/unfriendly, cruel/

kind, passive/active, and complex/simple. The authors define positive self-concept as the overall positive evaluation that a person makes of herself. Incongruence as used in this study measures the difference between the individual's actual self-perception and the way she would like to be. High scores indicate the likelihood of considerable anxiety and social maladjustment. For example, the mother who sees herself as cruel but wants to be kind might experience heightened anxiety in caretaking activities and would most likely be particularly stressed in disciplinary situations where cruel feelings might be evoked. Internal inconsistency of self-concept refers to the variability of percepts that comprise the overall positive evaluations. A tendency to endorse items, such as friendly and cruel at the same time, indicates no firm sense of personal identity and a likely behavioral pattern of impulsive and unstable interactions. Split-half reliability of the SCIS was .83. Construct validity was established by administration with the Tennessee Self-Concept Scale to 175 subjects. Correlation patterns between scores on the two tests were as follows: total positive, .934 ($P < .001$); incongruence, .824 ($P < .001$); and inconsistency, .771 ($P < .001$).[9]

The SIV consists of six scales, defined by the authors as follows:

1. Support: "being treated with understanding, receiving encouragement from other people, being treated with kindness and consideration."
2. Conformity: "doing what is socially correct, following regulations closely, doing what is accepted and proper, being conformist."
3. Recognition: "being looked up to and admired, being considered important, attracting favorable notice, achieving recognition."
4. Independence: "having the right to do whatever one wants to do, being free to make one's own decisions, being able to do things in one's own way."
5. Benevolence: "doing things for other people, sharing with others, helping the unfortunate, being generous."
6. Leadership: "being in charge of other people, having authority over others, being in a position of leadership or power."

The SIV questionnaire consists of 20 sets of three statements each, such as "to be free to do as I choose, to have others agree with me, and to make friends with the unfortunate." Subjects are asked to rate which statement is most important to them, which one is least important, and to leave one statement blank. Reliability was established by Kuder-Richardson analysis with values ranging from .71 to .86. Construct validity was established by comparison with various other self-report personality measures, such as the Allport, Vernon, Lindzey Study of Values, where correlations ranged from −.48 to .59.[10]

The data collected for the study were analyzed by two one-tailed t tests of the differences between mean scores for the experimental and control groups. The first of these procedures was used to analyze the self-concept data and the second was used to analyze the values data. Analysis of the values data also used a two-factor analysis of variance procedure to test for significant differences among the six interdependent value scales. The two factors used were the type of subject and the type of value.

RESULTS

Statistical analyses of differences between the two groups of mothers showed no significant differences in background characteristics, indicating that the women were essentially comparable in terms of demographic factors, such as age, number of marriages, number of children, age of child, educational level, race, income, occupation, and marital status (Tables 1 and 2).

Significant differences were found, however, in terms of the self-concept and interpersonal values variables. The self-concept data indicated that the women who abused their children had lower and more inconsistent self-concepts than the nonabusers, and that they experienced a greater disparity (incongruence) between the way they viewed themselves and the way they would like to be (Table 3).[11]

The values data indicated that the abusive women valued conformity and benevolence less, and authority over others more than did their nonabusive counterparts. No significant differ-

ences were found in the valuing of support, recognition, and independence (Tables 4 and 5).[12]

COMMENT

Conflicts between personal values and environment conditions will, to a large extent, determine the degree to which a person experiences stress and responds to it.[10-15] Thus, the abusive mother, who finds little gratification in the performance of benevolent and nurturing tasks, may experience in exaggerated form the various psychological and economic stresses of child rearing.

A low conformist value structure associated with the rejection of rules, regulations, and cultural proprieties may prevent the abusive woman from successfully fulfilling her role as a mother. Furthermore, abusive women in this study scored significantly lower on two of the three scales (conformity and benevolence) that are characterized by high scores for the general female population.[10] As defined in this study,[10] leadership refers to the subject's need for authority and control rather than her empathy with the potential object's need for guidance. When this value is not fulfilled, power needs that are blocked in the public domain may be returned with renewed vigor to the domestic arena.[15]

Self-concept variables, as aforementioned, also influence the individual's perception of a particular experience. Thus, the abusive woman is likely to possess a negative and unstable sense of self that she seeks to modify through an idealized image of parenting that is integrated neither with her personality nor her value system.[4] The mothering experience may then become a vicious circle of failure and frustration that she tries to conceal or deny so that little corrective input is available to her.

That these are statistical data and do not negate the critical role of individual differences among abusive women is of some importance. Indeed, the physician's task of carefully observing and listening for such variations becomes even more important in view of the patient's intense need for individual attention and concern. Furthermore, the characteristics of abusive mothers described in this study reflect values and self-concept perceptions at only one point in time and may therefore be sequelae of the abusing situation rather than permanent traits. In delineating the current status of such women, however, the results guide us toward appropriate interventions in their present lives.

These findings and their relationship to the primary care physician are outlined in Table 6. The demonstrated combination of low self-concept and high self-concept incongruence makes it essential that the pediatrician carefully balances his or her supportive-

Table 6.—Characteristics of Abusive Mothers—Implications and Interventions

Trait	Implication	Intervention
Low self-concept	Sees self negatively; expects failure and censure; feels guilty and inadequate	Convey respect for her capacities, interests, and successes; praise when appropriate
High self-concept incongruence	Has high and unrealistic expectations of self and child; is very sensitive to criticism	Attend carefully to unrealistic expectations; praise moderately to avoid fear of reporting problems; urge and support parent education classes
High self-concept inconsistency	Has no firm sense of self; cannot convey stable image to child; may have difficulty following through consistently	Set modest and simple goals; check frequently on progress (frequent office visits and phone calls)
Low conformity	Resents rules and regulations; feels underlying hostility to authority and social demands	Solicit her opinion; develop goals together rather than as external authority
Low benevolence	Has difficulty deriving pleasure from nurturant behavior; may find child care unsatisfying	Set modest goals; encourage other activities; advocate for and support use of professional child care and relatives
High leadership	Enjoys authority over others; may seek authority exclusively over child	Encourage other activities for mother and child; educate on child's developmental need for self expression

ness and positive feedback against the danger of fostering ever higher and more unrealistic expectations in the mother. Excessive or unwarranted praise may generate even more guilt and frustration if the child fails to meet the desired standard.

Support can be most productively offered through clear acknowledgment of potential difficulties together with praise within the context of the mother's own effort. For example, an overly enthusiastic "your baby gained 2 lbs this month" focuses solely on the child and might set up an expectation that could later prove frustrating; whereas "your baby is doing fine this month, how are things going with you" praises the child but also invites the mother to share more of her feelings about what the improvement meant for her. Unrealistic expectations are mitigated by such general comments that focus on actual gains rather than ideal standards.

Anticipating potential difficulties is also important. The pediatrician may minimize the mother's sense of failure if a new approach does not work immediately by such comments as, "it may take a while before you notice changes," or "don't worry if it doesn't work right away." Although such statements may seem obvious, it is likely that the abusive mother needs such cognitive input to balance the highly idealized expectations that are reflected in the self-concept incongruence data. Parent education classes may be particularly useful here, and may even be run within the practice by a nurse practitioner, a graduate student, or another trained person.[16] This may reduce the social stigma as well as financial stress that a formal therapy referral would entail.

The inconsistency of self-concept described in this study offers the pediatrician an extremely important opportunity to help the abusive mother begin to focus on simple but consistent goals in regard to child care. Again, the physician can encourage discussion of the many changing moods the mother may experience by statements, such as, "There may be days when feeding your baby will be fun, but there will also be days when you'll have less patience and find it irritating." Setting modest goals that can be consistently worked on is critical here, and the abusive mother should be encouraged to call or visit the office when questions or problems arise. Regular office visits should be scheduled more often as well, both to monitor the child's progress and to intensively support the mother's efforts.

Abusive women in this study were as desirous of support and recognition as nonabusive mothers. This suggests that, although the needs of abusive mothers are not unlike those of other mothers, the pediatrician's support of maternal self-image and nurturing behaviors should be emphasized at each office visit.

The finding that the values of abusive women do not correlate with standard sex differences should lead the pediatrician to become familiar with community day care resources and to encourage the mother to develop interests outside the home without undue guilt. This may be done by briefly expressing interest in other than child-related aspects of her life, as well as by direct statements about the usefulness of spending some time apart from the child during the week.

The abusive mother's likely resistance to rules and regulations, and her own need for leadership, make it imperative that the pediatrician avoid an overly authoritarian posture. Advice may be indirectly offered by statements, such as "have you tried . . ." or suggested, as in "you might want to try . . .," rather than by judgmentally pronounced statements, such as "you should . . . ." Similarly, the mother's interpretation of her child's behaviors should be solicited whenever possible, so that goals are developed together. In modeling this sort of interaction, the pediatrician may also indirectly pave the way for a less authoritarian relationship between the mother and her child, with greater tolerance on her part for the child's developing need for self-assertion.

The primary care physician potentially may play a critical role in ameliorating abuse. Whereas many of these abusive women would not follow through in traditional psychotherapy, they may be accessible to the supportive role of their child's pediatrician. In addition to the medical management of the child, the physician can provide the mother with both factual information on child rearing and more realistic expectations of maternal functioning. He or she can play a role in increasing self-concept congruence by helping the mother lower her expectations and by ameliorating guilt she might feel at not being satisfied with her role. The services of a pediatric practice may be integrated with those of the community in such a way as to encourage development of the mother's need for control or power in areas outside the home. •

Disparate Cultures of Middle Ear Fluids

Results From Children With Bilateral Otitis Media

Stephen I. Pelton, MD; David W. Teele, MD; Paul A. Shurin, MD; Jerome O. Klein, MD

• Cultures of middle ear fluids (MEFs) are needed to determine both efficacy of antibiotics and vaccines, and microbiologic outcome of otitis media (OM). We reviewed data on 221 children, aged 2 months to 12 years; 122 had acute otitis media (AOM), 99 had asymptomatic MEF. We included only *Streptococcus pneumoniae, Haemophilus influenzae, Branhamella catarrhalis,* and *Staphylococcus aureus* as pathogens. Of children with AOM, MEF was sterile or contained nonpathogens in both ears in 51, and one or more pathogens in 71. Of these 71, 40 had the same pathogen or pathogens in both ears; 25 patients had a pathogen in one ear and sterile fluid or only nonpathogens in the other; four patients had a different pathogen in each ear; and two patients had two pathogens in one ear and only one in the other. Of those with asymptomatic MEFs, in 80 the effusion was sterile or contained only nonpathogens in both ears, and in 19 contained one or more pathogens. Of these 19, ten had the same pathogen isolated from both ears; nine had a pathogen in one ear and sterile fluid or only nonpathogens in the other. Thus, in 31 children with AOM and nine with asymptomatic MEFs, results of cultures of MEF were different.

(*Am J Dis Child* 134:951-953, 1980)

The bacteriology of otitis media (OM) had been studied by needle aspiration of middle ear fluids (MEFs). Results of many such studies are remarkably consistent: *Streptococcus pneumoniae*, nontypable strains of *Haemophilus influenzae*, and group A streptococcus are the principal pathogens isolated from MEF. Isolation of one of these organisms from MEF is considered diagnostic of bacterial OM. Investigations of antimicrobial agents or vaccines rely on results of initial and subsequent cultures of MEF to evaluate microbiologic efficacy.

We noted frequent disparate results from cultures of aspirates of MEF obtained from children with bilateral OM. Such disparity may compromise microbiologic studies of OM. To determine the frequency and type of disparate results, we reviewed results of bacterial cultures of MEF from children with bilateral effusion in the middle ear.

MATERIALS AND METHODS

We reviewed results of bacterial cultures of MEF for all children with bilateral effusion of the middle ear who participated in one of three investigations conducted by us. Ninety-nine patients were included in a randomized study that compared the efficacy of sulfamethoxazole-trimethoprim or ampicillin sodium for acute OM.[1]

Forty children participated in a study to evaluate the efficacy of pneumococcal vaccine in children with recurrent episodes of acute OM (D.W. Teele, MD, J.O. Klein, MD, unpublished data, 1980) and the remaining 82 children were part of a study of the microbiology of persistent effusions of the middle ear.[2,3]

Preliminary cultures of the external auditory canal were performed using a nasopharyngeal swab. The external auditory canal was then sterilized using a 70% alcohol solution for 60 s. Alcohol was removed with a blunt-tip (Baron) aspirator and tympanocentesis was performed using a suction trap (Senturia) aspirator. The MEF was processed in the Microbiology Laboratory at Boston City Hospital. Material was inoculated onto blood, chocolate,

and eosin methylene blue agar, and into blood and chopped meat broth. Bacterial isolates were identified by routine methods and isolates of *Strep pneumoniae,* and *H influenzae* were typed using, respectively, Danish antisera and polyvalent- and type-specific antisera obtained from the Center for Disease Control, Atlanta.

Patients were classified as symptomatic or asymptomatic based on clinical information at the time of aspiration. Those children with earache, fever, irritability, anorexia, vomiting, or diarrhea were considered to have acute OM. Those children without such symptoms were classified as having asymptomatic MEF.

RESULTS

The results of bacterial cultures of external auditory canal and MEF were available for 67 children with acute OM (Table 1). *Haemophilus influenzae, Strep pneumoniae,* and *Branhamella catarrhalis* were found in the MEF but not in the external canal in 94%, 91%, and 100% of the paired specimens. In contrast, *Staph aureus, Staph epidermidis,* and diphtheroids were usually present in the external auditory canal only or in the canal and MEF, and uncommonly in the MEF alone.

From these data we have concluded that isolation of *Strep pneumoniae, H influenzae,* or *B catarrhalis* from MEF indicates primary infection (pathogens), whereas isolation of *Staph aureus, Staph epidermidis,* or diphtheroids frequently represents contamination of MEF by organisms present in the external canal (nonpathogens).

Tympanocenteses were performed on both ears of 221 children aged 2 months through 12 years; 122 had acute OM, whereas 99 had asymptomatic MEF.

Cultures of MEF of both ears of children with acute OM had the following results: sterile MEF or the presence of nonpathogens in 51 (42%); 71 children (58%) had one or more pathogens isolated from cultures of MEF (Table 2). Forty of these children had the same pathogen or pathogens isolated from aspirates of both middle ear effusions: 22 had *Strep pneumoniae* in both MEF specimens, 15 had nontypable *H influenzae,* one patient had *B catarrhalis,* and two patients

had both *Strep pneumoniae* and nontypable *H influenzae* in each culture. In 31 (25%), the results were disparate: 13 patients had a pathogen in one ear and sterile fluid in the other, 12 patients had a pathogen in one ear and a nonpathogen in the other, four patients had a different pathogen in each ear, and two patients had nontypable *H influenzae* and *Strep pneumoniae* in one specimen of MEF and only one pathogen in the other.

Results of culture of MEF of both ears of children with asymptomatic MEF included sterile fluid or the presence of nonpathogens in 80 (81%) (Table 3). In 19 children (19%), pathogens were recovered from one or both middle ear effusions: ten children had the same pathogen isolated from aspirates of both middle ear effusions; five had nontypable *H influenzae* isolated from both middle ear specimens; four had *Strep pneumoniae* in each specimen; and one had *B catarrhalis* in each ear. In nine (9.1%), the results were disparate: five patients had a pathogen in one middle ear effusion and sterile fluid in the other, four had a pathogen isolated from one ear and a nonpathogen from the other.

Thus, analysis based on results of only one of the cultures of MEF would have been misleading in 22% of children with acute OM and 9.2% of children with asymptomatic MEF.

COMMENT

Disparity in cultures of MEF has been reported by only a few investigators. Grönroos reported 31.6% disparate results of cultures from children with bilateral OM.[4] All children had either *Strep pneumoniae, H influenzae*, or group A streptococci recovered from one MEF and sterile fluid in the other. Van Dishoeck found 19% of cultures from children with bilateral OM yielded different results.[5] The majority of children had a pathogen recovered from one ear and sterile fluid in the other. Also included were six cases in which cultures of one MEF yielded a single pathogen and the opposite MEF two pathogens. Austrian et al have recovered different serotypes of *Strep pneumoniae* in 1.5% of their cases of bilateral pneumococcal OM, but make no reference to disparate results.[6]

Our results are a minimal estimate of disparity. We chose only those bacterial species commonly recognized as pathogens: *Strep pneumoniae, H influenzae, B catarrhalis*, and *Strep pyogenes*. In 25% of children with bilateral acute OM and 9.2% of children with asymptomatic but persistent middle ear effusion, results were disparate. The frequency of disparate results observed in acute OM and asymptomatic MEF that we observed reflects the frequency of bacterial isolates in each classification. Although 25% of the children with acute OM and 9% of children with asymptomatic effusion had disparate results, if only cases of bacterial otitis are considered the frequency of disparity (43.6% vs 47.0%, respectively) is similar. These data pose a critical problem in the evaluation of efficacy of vaccines or chemotherapeutic agents used to prevent or treat disease of the middle ear. In children with bilateral disease, both ears must be evaluated, both initially and at conclusion of therapy.

Needle aspiration of MEF for microbiologic diagnosis to guide antimicrobial therapy is indicated for children with acute OM in selected circumstances: if the child is critically ill when first seen, if the child fails to respond appropriately to therapy, and for the newborn infant or child with altered host defenses who may be at risk for infection with unusual bacteria. The high incidence of different results in cultures of effusion in bilateral acute OM indicates that tympanocentesis of both ears must be performed to be certain of the microbiologic diagnosis.

Finding disparate results in a bilateral disease has not been reported in pyelonephritis, pneumonia, or diseases, such as osteomyelitis or septic arthritis, when multiple foci have been present, and may be unique to middle ear disease. Its implication may be that malfunction of the eustachian tube and reflux of nasopharyngeal secretions is the primary event in the pathophysiology of OM, and the proliferation of bacteria is secondary. The isolation of *Strep pneumoniae* and *H influenzae* from 70% of cases of bilateral OM suggests that not all bacterial species that colonize the nasopharynx are equally likely to be isolated from middle ear effusion. These pathogens may have unique properties that enable them to survive host defenses once they have gained access to the middle ear cavity.

Nasal Deformities in Neonates

Their Occurrence in Those Treated With Nasal Continuous Positive Airway Pressure and Nasal Endotracheal Tubes

Kusuma Gowdar, MD; Marilyn J. Bull, MD; Richard L. Schreiner, MD; James A. Lemons, MD; Edwin L. Gresham, MD

• Seventy-two infants were treated with nasal continuous positive airway pressure for one day to five weeks, and nasal deformities developed in none. One hundred thirty-six infants were treated with nasotracheal tubes and eight (6%) were found to have nasal deformities. There was a strong correlation between duration of intubation and birth weight and the presence of deformities. In no infant receiving ventilation therapy for less than six days did nasal deformities develop. The incidence of nasal deformities in infants weighing less than 1,000 g was 50%, whereas in infants heavier than 1,000 g it was 2.4%. No infant had clinical symptoms suggestive of subglottic stenosis during the first year of life. The data do not support the use of routine tracheostomy in newborn infants even after prolonged intubation.

(*Am J Dis Child* 134:954-957, 1980)

Mechanical ventilation has dramatically improved the survival of neonates with severe respiratory distress during the past ten years. However, its use has significant complications. A number are directly related to endotracheal tubes, especially subglottic stenosis[1,2] and tracheal,[3] esophageal,[4] and pharyngeal[5] perforation. The type of endotracheal tube, whether nasal or oral, is important in determining the type of complication. Oral tubes have an increased risk of traumatic cleft palate[6,7] and gingival and dental complications,[8] whereas nasal tubes are most frequently associated with nasal deformities[9-11] and infections.[12,13] We investigated the incidence of nasal deformities and subglottic stenosis in a large series of infants treated with nasal continuous positive airway pressure (CPAP) tubes, nasal endotracheal tubes, or both.

SUBJECTS AND METHODS

All infants treated for respiratory distress with nasal CPAP or nasotracheal intubation and ventilator therapy during the period of Oct 1, 1976 through Sept 30, 1977, were studied. Mechanical ventilation was carried out via a nasotracheal tube using a straight polyvinyl chloride (Portex) tube without a cuff. A 3.5-mm tube was used for full-term infants and a 3.0-mm tube for most premature infants. In infants weighing less than 1,250 g, a 2.5-mm tube was occasionally used. The endotracheal tubes were lubricated with xylocaine ointment before intubation. After application of benzoin to the cheeks, the tube was fixed with a strip of 1-cm adhesive tape around the neck (Fig 1). Infants requiring nasal CPAP were treated with polyvinyl chloride (Argyle) nasal CPAP tubes (small size for infants weighing $< 1,500$ g and large size for those weighing $> 1,500$ g). Nasotracheal tubes were not routinely changed. Corticosteroids and racemic epinephrine were rarely used after extubation. All infants were followed up in the newborn follow-up clinic until at least 1 year old (corrected for gestational age). During each visit, the nose was examined for evidence of nasal deformity.

RESULTS

Three hundred seventy infants required nasal CPAP, nasotracheal intubation, or both during the one-year period. One hundred seven of the infants died in the newborn intensive care unit or after discharge. Two of these had nasal deformities. Of the 263 survivors, 208 cases were followed in the newborn follow-up clinic program and constitute the basis of this study. Seventy-two infants were treated with nasal CPAP alone for a period of one day to five weeks: 67 infants for seven days or less; four infants, eight to 21 days; and one infant, five weeks. None of these infants had nasal deformities on follow-up examination.

One hundred thirty-six infants were treated with nasotracheal tubes. Fifty-seven of these infants also had nasal CPAP before or after extubation. Eight of the 136 infants (6%) were found to have nasal deformities (Table 1). There was a strong correla-

1-7	119	3 (2.5)
> 7	17	5 (29)
8-15	10	2
16-21	1	1
22-28	2	0
29-42	3	2
> 42	1	0

tion with the duration of nasotracheal intubation and the presence of nasal deformities (Table 2). One hundred nineteen infants underwent nasotracheal intubation for seven days or less; three (2.5%) had nasal deformities, all of whom had been receiving ventilation therapy for six or seven days. No infant receiving ventilation therapy for less than six days had a nasal deformity. Seventeen infants received nasotracheal intubation for eight or more days, and five of these (29%) had nasal deformities. The difference between the incidence of nasal deformities in infants receiving ventilation therapy for seven days or less and in those receiving ventilation therapy for more than seven days is significant ($P < .001$).

Five of the infants with nasal deformities weighed less than 1,000 g at birth; since ten infants weighing less than 1,000 g received ventilation therapy, survived, and were followed up in the clinic during the study period, this represents a 50% incidence of nasal deformities in infants weighing less than 1,000 g. The incidence of nasal deformities in infants heavier than 1,000 g was 3:126 (2.4%). The difference is significant ($P < .001$). None of the eight infants with nasal deformities had a history of frequent otitis media in the first year of life. All of the deformities involved either scarring of the ala nasi (Fig 2), loss of cartilage of the ala nasi or nasal stenosis (Fig 3), or minimal loss of the tip of the nasal septum. In addition, no infant had clinical symptoms suggestive of subglottic stenosis and no infant required tracheostomy.

COMMENT

This report presents, to our knowledge, the largest series of infants followed up after nasotracheal intubation. It is obvious from our data that nasal deformities in our institution are correlated with very low birth weight (< 1,000 g) and prolonged nasotracheal intubation (longer than five days). In no patient ventilated for less than six days did nasal deformities develop. Most authors,[1,12] but not all,[14] have found that the duration of intubation correlates with the severity of laryngeal and nasal lesions. However, Choffat et al found that the duration of intubation did not correlate with the incidence of laryngeal

Fig 3.—Stenosis of right nostril secondary to nasotracheal intubation.

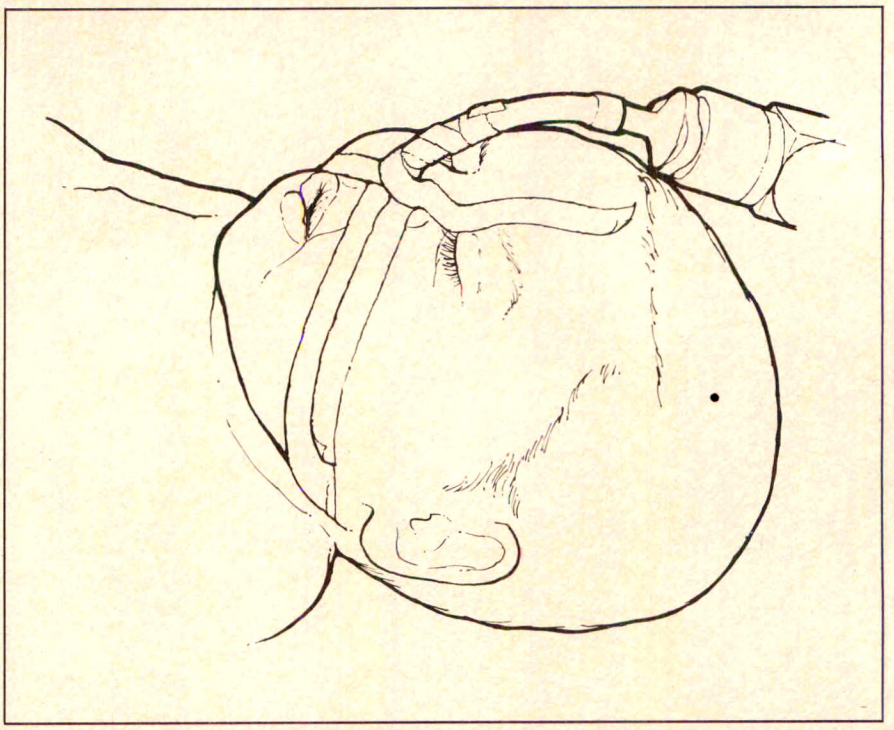

Fig 4.—Nasotracheal tube extending in cephalad direction rather than caudally. This may account for some nasal trauma with nasotracheal tubes.

and tracheal lesions in infants with endotracheal intubation,[14] and Baxter et al did not find a significant correlation between the incidence of nasal lesions and the duration of nasotracheal intubation.[11] However, none of the 49 neonates of Choffat et al weighed less than 1,000 g; only one of the patients of Baxter et al had a birth weight less than 1,000 g, and seven of their other nine patients had a birth weight of 1,000 g to 2,000 g. Thus, their data are significantly different from ours in that we had no cases of nasal deformities in infants weighing between 1,000 and 2,000 g.

The three infants in whom deformities developed with seven days or less of intubation were relatively large. This might be related to increased movement in these infants, compared with smaller infants. Whether respiratory paralysis might decrease the risk of nasal trauma is speculative. One of our three infants who received ventilation therapy, who weighed more than 2,000 g and in whom nasal trauma developed, received a paralytic agent (tubocurarine chloride), whereas the other two did not.

In the past, many authors recommended that endotracheal tubes be changed periodically, but more recently most authors recommend changing the endotracheal tube only for clinical indications, such as accidental displacement or plugging of the tube. The incidence of nasal trauma might be decreased by replacing endotracheal tubes every six to seven days. However, the trauma that may occur at the time of actual intubation—to the gingival, pharyngeal, laryngeal, and subglottic areas—may be more important than the minimal risk of nasal trauma with prolonged intubation.

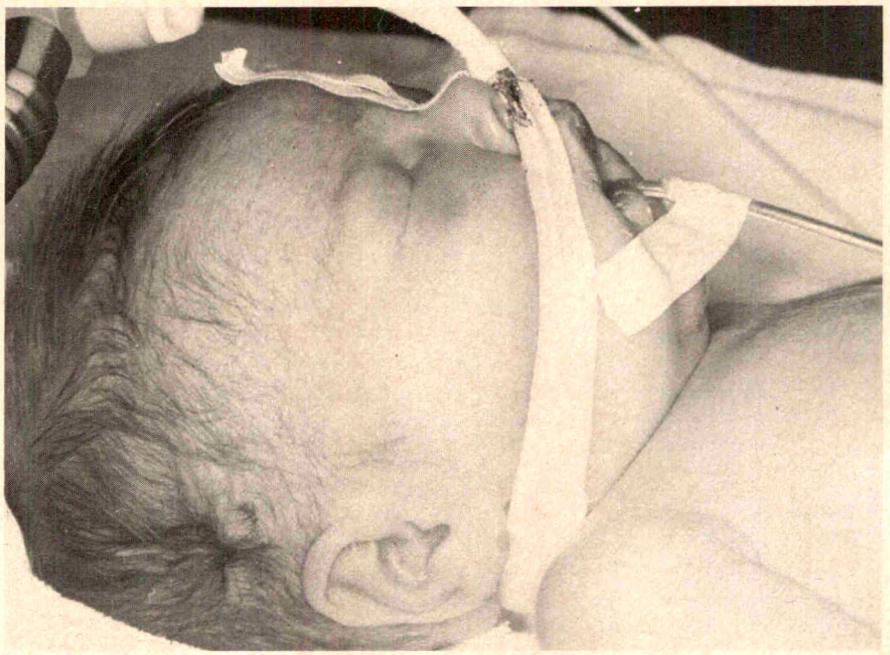

Fig 5.—Tape exerting pressure on nasal septum. This may result in loss of tip of nasal septum, especially in very low-birth-weight babies.

The low incidence of nasal lesions in infants heavier than 1,000 g (2.4%), the fact that the lesions involved only the alae and tip of the septum but not major loss of nasal septal cartilage,

and the absence of clinical problems with subglottic stenosis suggest to us that nasotracheal intubation should be continued. These infants were followed up until a corrected age of 1 year; it is, of course, possible that some cases of subglottic stenosis might occur later and, therefore, be missed by this study.

The high incidence of nasal deformities in infants weighing less than 1,000 g is disturbing. It might be possible to decrease the incidence of these lesions by fixing the tube in the direction of the infant's mouth (Fig 1) rather than in the cephalad direction (Fig 4). Allowing the tube to exit the nose in this direction might decrease the risk of trauma to the nasal alae. To do this for infants in incubators, it is preferable to bring the respirator tubes through the porthole at the foot side of the incubator rather than through the head side. In fact, maintaining the endotracheal tube in this position was first suggested by Pettett and Merenstein.[15] It might also be useful to replace the nasotracheal tube to the other nostril every seven days. Whether this would decrease the incidence of nasal trauma with prolonged intubation is, of course, speculative. Routine daily cleansing of the nostrils, with removal of crusted material and other debris, might also be helpful. Positioning the tape so that it does not exert pressure at the tip of the nasal septum (Fig 5) might prevent trauma at this site.

There is controversy over the relative advantages of nasotracheal and orotracheal intubation. A major advantage of the nasotracheal tube seems to be the decreased risk of accidental extubation. However, other authors believe that with proper precaution and fixation of orotracheal tubes, the risk of accidental extubation is no greater than with nasotracheal tubes.[16] To our knowledge, there are no data to support either side of the argument.

Because of the reports of laryngotracheal lesions with prolonged intubation in the newborn, some investigators have recently advocated the use of tracheostomy in infants requiring intubation for longer than one week.[17] However, this has not gained wide popularity and is unlikely to do so because of the disastrous results of tracheostomy in years past. One author suggested that with modern means of inserting and managing tracheostomy in neonates, the complication rate is only 8%.[17] However, their study included only 25 subjects. It is interesting that of the ten infants from 28 to 30 weeks' gestation, only one survived. Therefore, their data does not support the use of tracheostomy in very low-birth-weight infants. In fact, we know of no data that support the use of tracheostomy in infants weighing less than 1,000 g. We believe the article by Filston et al places the role of tracheostomy in infants in proper perspective, ie, its routine use in the newborn intensive care unit seems unwarranted, even after intubation for longer than seven days.[18]

Fluid Administration and Bronchopulmonary Dysplasia

The Lack of an Association

Robert C. Spahr, MD; Alan M. Klein, MD; David R. Brown, MD; Ian R. Holzman, MD; Hugh M. MacDonald, MD

• The fluid intake of 38 surviving infants with severe respiratory distress syndrome was evaluated. There were no substantial differences in fluid administration between those in whom bronchopulmonary dysplasia (BPD) developed and those in whom it did not. The factors that were associated with the development of BPD were the degree of prematurity, patent ductus arteriosus, pulmonary air leak, exposure to high concentrations of oxygen, and use of ventilation at faster rates.

(*Am J Dis Child* 134:958-960, 1980)

A recent report[1] suggested that there is an association between fluid intake during the first five days of life and the development of bronchopulmonary dysplaisa (BPD). To address the possibility of such an association, we examined data from infants who were treated with mechanical ventilation for respiratory distress syndrome (RDS).

PATIENTS AND METHODS

We recorded the noncolloid fluid intake (the sum of parenteral and enteral fluid administered), amount of blood products administered, daily weight, and use of phototherapy for all 69 infants with severe RDS who were admitted to our nursery during the 12-month period ending in December 1978. Fluid intake was expressed as milliliters per kilogram per day using the infant's weight at the beginning of the 24-hour period. Changes in weight were expressed as percent of birth weight.

Ventilation of all patients was supported with a time-cycled, pressure-limited ventilator that used unwarmed, humidified gas at relatively low pressures and rates as well as either a 1:2 or a 2:1 inspiratory to expiratory (I/E) ratio. They received care in servocontrolled incubators, with heat shields in the incubators for those infants weighing less than 1,200 g.

The diagnosis of bronchopulmonary dysplasia was made in patients in whom the typical roentgenographic findings[2] were made and who had a continuing supplemental oxygen requirement at 1 month of age. Pulmonary air leak was defined by roentgenographic evidence of pulmonary interstitial emphysema, pneumomediastinum, or pneumothorax. Patent ductus arteriosus (PDA) was diagnosed on the basis of the classical murmur in association with collapsing pulses; a marked PDA was one that was symptomatic to the degree that the clinical staff initiated therapy with furosemide and/or digoxin for treatment of congestive heart failure.

For purposes of analysis, the patients were divided into two groups. Group 1 comprised those patients with RDS in whom BPD did not develop, while group 2 comprised those with RDS in whom BPD did develop. χ^2 test, Student's t test, and Wilcoxon's rank sum test were used to evaluate statistical significance. A $P < .05$ defined statistical significance.

RESULTS

Of the 69 patients entered into the study, 39 lived longer than 28 days. The data from 38 of these survivors were analyzed. The patient excluded from the analysis was transferred to another nursery at 5 days of age when he no longer required mechanical ventilation. There were 29 patients in group 1 and nine in group 2. Patients in group 2 had significantly lower birth weights ($P < .02$, Wilcoxon's rank sum test) and gestational ages ($P < .01$) (Table 1). No significant differences existed between the groups

for place of birth (inborn vs outborn), sex, asphyxia, and the use of phototherapy. At the time of entry into the study, the severity of the RDS was similar for the groups as indicated by clinical findings, chest roentgenograms, and alveolar-arterial oxygen difference values taken at 6 hours of age (Table 1).

There were no significant differences in fluid intake or in weight gain between the groups (Table 2). Since the occurrence of BPD was more common in lower-birth-weight infants, we compared fluid intake for infants weighing less than 1,800 g in each group. The mean daily noncolloid intake for these lower-birth-weight infants in group 1 (n = 15) was 111 mL/kg/day; for group 2 infants weighing less than 1,800 g (n = 8), it was 114 mL/kg/day during the first 7 days of age. Mean total fluid intake for lower-birth-weight infants of group 1 was 115 mL/kg/day, and for group 2 infants weighing less than 1,800 g it was 123 mL/kg/day during the first week of age.

However, there were differences between the groups in the incidence of PDA and pulmonary air leak and in the ventilator settings (Table 1). Four patients in group 2 and one in group 1 had significant PDA ($P < .01$). Pulmonary air leak occurred four times in group 2 and three times in group 1 ($P < .05$). Infants in whom BPD developed were exposed to 101 ± 17 hours (mean ± SEM) of fraction of inspired oxygen greater than 0.40 while receiving mechanical ventilation during the first week compared with 21.4 ± 4.9 hours for group 1 ($P < .001$). Those in whom BPD developed were treated with ventilator rates of more than 25 cycles/min for 53.0 ± 15.5 hours compared with 6.4 ± 2.1 hours for group 1 ($P < .01$). There were no significant differences between the groups in end-expiratory pressures and inspiratory pressures used. The different I/E ratios did not influence the development of BPD.

COMMENT

Many factors have been associated with the development of BPD. These include prolonged exposure to high concentrations of oxygen,[2] endotra-

cheal intubation,[3] exposure to high, peak inspiratory pressure during mechanical ventilation,[4] PDA,[5] and decreased availability of antioxidant substances.[6] Our patients in whom BPD developed had longer exposure to high concentrations of oxygen and had higher incidences of PDA and pulmonary air leak than patients in whom BPD did not develop.

Recently, Brown et al[1] reported that infants in whom BPD developed had received considerably more fluid during the first five days of life compared with those in whom BPD did not develop. They treated 43 infants with ventilation, in seven of whom BPD developed. These authors suggested that the increased fluid intake may be "edemagenic" and may contribute to the development of BPD. We did not find a significant increase in fluid administration to those patients in whom BPD developed. Our patients with BPD had a mean daily total fluid intake of 123 ± 10 mL/kg/day compared with 114 ± 3.3 mL/kg/day for the other group. Fluid retention, despite conservative fluid administration in group 2, is unlikely since there were no significant differences in weight gain between the groups (Table 2). It is difficult to resolve the discrepancies between our study and that of Brown et al.[1] There may have been basic differences in patient populations since all of the patients in the study of Brown et al who had BPD also had PDA, while only four of our nine patients with BPD also had PDA. The conclusions of both studies are based on small numbers of patients with BPD, and data from more patients are required to define with certainty the role of fluid administration in the development of BPD.

It would appear that if fluids are administered at conservative rates (110 to 125 mL/kg/day), factors other than fluid intake are more important in the development of BPD. In our patients with severe RDS who were receiving mechanical ventilation, these factors were the degree of prematurity, pulmonary air leak, PDA, prolonged exposure to high concentrations of oxygen, and ventilation at faster rates.

Hyperfunctioning Thyroid Nodules in Children

Kazuo Abe, MD, PhD; Mutsuko Konno, MD; Takuji Sato, MD; Nobuo Matsuura, MD

• We studied two cases of hyperfunctioning thyroid nodules in children. A 9-year-old girl and an 11-year-old girl had thyroid masses in otherwise nonpalpable thyroid glands. Scintiscan showed hyperfunctioning thyroid nodules. The former patient had elevated values for T_4 and T_3, and plasma thyrotropin (TSH) level failed to respond to stimulation with thyrotropin releasing hormone (TRH), whereas the latter patient had normal values for T_4 and T_3 and plasma TSH response to TRH was normal. After the surgical removal of nodules, scintiscan exhibited radioactivity in the contralateral lobe of the thyroid gland in the former and in the ectopic thyroid tissue in the latter. Results of microscopic examinations of thyroid nodules were consistent with adenomatous goiter.

(*Am J Dis Child* 134:961-963, 1980)

Reprint requests to Department of Pediatrics, Hokkaido University School of Medicine, Kitaku, N 15 W 7, Sapporo, 060, Japan (Dr Abe).

The hyperfunctioning thyroid nodule is very rare in children, although not unusual in adults. To our knowledge, only nine children with this disease have been reported in the literature.[1-6] We studied two patients with hyperfunctioning thyroid nodules and reviewed briefly nine recorded cases of this disorder in childhood.

REPORT OF CASES

CASE 1.—A 9-year-old girl was admitted to the hospital because of a swelling in her neck. On admission, a firm 2.5 × 3.5-cm nontender nodule was felt in the right lobe of the thyroid. There were no palpable regional lymph nodes. Pulse rate was 120 beats per minute and blood pressure was 128/80 mm Hg. No eye signs of Graves' disease were noted. There were no tremor, palpitation, sleep disturbance, excessive sweating, or other symptoms of thyroid dysfunction.

Results of thyroid function studies showed elevated plasma triiodothyronine (T_3) and thyroxine (T_4) levels, which were 246 ng/dL and 16.2 μg/dL, respectively (Table 1). The thyroid uptake with ^{131}I was 31% after 24 hours. The thyroid scan showed all radioactivity confined to the palpable nodule (Figure). The patient was stimulated with 10 units of bovine thyrotropin (TSH) given intramuscularly on three consecutive days. The thyroidal ^{131}I uptake at 24 hours rose to 59.8% and a slight additional uptake was demonstrated in the left lobe, indicating the existence of the extranodular suppressed tissue of the thyroid (Figure). After the oral administration of 75 μg of T_3 for eight days, the thyroid uptake with ^{131}I was 26.2% at 24 hours. Basal plasma TSH concentration was undetectable and plasma TSH level failed to increase after the intravenous administration of thyrotropin releasing hormone (TRH) in a dose of 5 μg/kg of body weight. Antibodies to thyroid microsomes or thyroglobulin were not detected.

Because of clinical and laboratory evidence of a hyperfunctioning thyroid nodule, a right thyroid lobectomy was performed. Microscopic examination of nodule was consistent with adenomatous goiter.

After operation, the patient was transiently hypothyroid, with a serum T_3 level

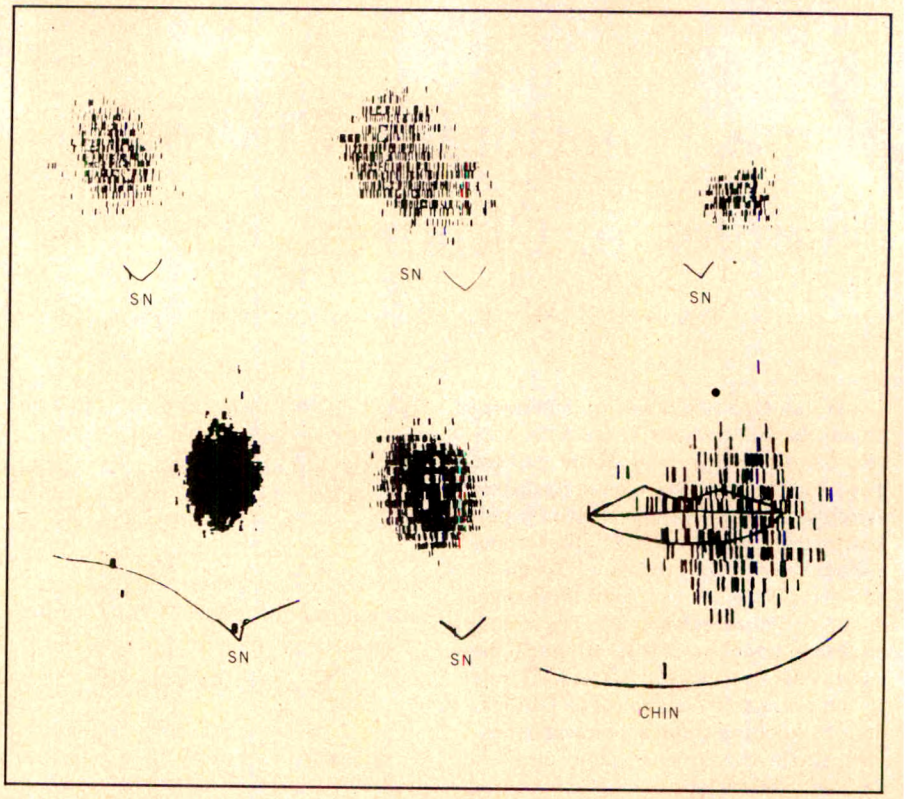
*TSH indicates thyrotropin; TRH, thyrotropin releasing hormone; AMA, antimicrosomal antibody; ATA, antithyroglobulin antibody; and ND, not detected.

of 90 ng/dL and a T_4 level of 4.2 μg/dL. Four months later, however, the patient was euthyroid chemically, with a T_3 level of 176 ng/dL and a T_4 level of 12.2 μg/dL. The thyroid scan revealed radioactivity in the left lobe of the thyroid. (Figure).

CASE 2.—An 11-year-old girl was admitted to the hospital because of a mass in the right side of the neck. She had been followed up every six months at another hospital for a small ventricular septal defect, when her pediatrician had noted a right thyroid mass.

On admission, a very firm 3 × 4-cm nontender mass was present in the area of the right lobe of the thyroid. Regional lymph nodes were not palpable. Pulse rate was 84 beats per minute and blood pressure was 100/60 mm Hg. There were no signs and symptoms suggestive of hyper- or hypothyroidism. Thyroid function studies showed normal plasma TSH, T_3, and T_4 levels of 2.5 μU/mL, 176 ng/dL, and 7.9 μg/dL (Table 1). The thyroid uptake with ^{131}I was 33.3% at 24 hours. The thyroid scan showed all radioactivity restricted to the nodule (Figure). After three days of TSH stimulation (10 units, twice a day), the 24-hour thyroidal ^{131}I uptake rose to 67.1%, and again the scintiscan showed radioactivity localized in the nodule; no function was visible in the extranodular thyroid tissue (Figure). After the administration of 75 μg of T_3 for seven days, the thyroidal ^{131}I uptake at 24 hours fell to 6.3% and there was no change in distribution of radioactivity on scintiscan. Plasma TSH concentration rose from 2.5 to 18.7 μU/mL after TRH stimulation. Antibodies against thyroid microsomes or thyroglobulin were not detected. Owing to the inordinate firmness of the nodule to palpation, surgical removal of nodule was performed. During the operation, the left lobe was found to be absent. Microscopic examination was compatible with adenomatous goiter.

Two weeks after surgery, the patient was chemically hypothyroid, with a T_3 level of 85 ng/dL, a T_4 level of 2.3 μg/dL, and a TSH level of 116 μU/mL, and the thyroid scan showed radioactivity in the mouth, indicating the presence of ectopic thyroid tissue (Figure). The patient has now been given 125 μg of thyroxine daily and carefully followed up. To date her health has remained satisfactory.



Radioiodine scintigrams of cases 1 and 2. Upper left, before therapy in case 1; upper middle, after thyrotropin (TSH) stimulation in case 1; upper right, ten days after operation in case 1. Lower left, before therapy in case 2; lower middle, after TSH stimulation in case 2; lower right, 14 days after operation in case 2. SN indicates suprasternal notch.

COMMENT

The hyperfunctioning thyroid nodule is uncommon in childhood. Case 1 represents a typical case of this disease. The thyroid scan revealed a "hot" nodule (defined as an area with increased uptake of radioactive isotope) independent of TSH control, as evidenced by failure of suppression of thyroidal ^{131}I uptake with T_3. Case 2, however, shows some unusual features. Although the thyroid scan demonstrated a hot nodule, the thyroid uptake of ^{131}I was suppressed by T_3, and plasma TSH levels significantly increased in response to TRH stimulation. These data were not compatible with those observed in most of adult patients with hyperfunctioning thyroid nodules.[7,8] Nevertheless, evidence of thyroid function was noted in the ectopic thyroid tissue on follow-up scintigram after surgical removal of the nodule. This finding is diagnostic of a hyperfunctioning thyroid nodule. Thus, it is tempting to explain the conflicting data by postulating incomplete TSH-dependence for the hot nodule, suppression of function in ectopic thyroid tissue prior to treatment, and congenital absence of the contralateral thyroid lobe. To our knowledge, only one patient similar to case 2 has been described in the literature, by Molnar et al.[9]

The clinical features of the hyperfunctioning thyroid nodule include swelling or mass in the neck and symptoms and signs of hyperthyroidism. In all of 11 children reported to date[1-6] with hyperfunctioning thyroid nodules, the initial complaint was only either a thyroid mass or a swelling in the neck.

The clinical picture of hyperthyroidism differs from that seen in Graves' disease. Symptoms and signs are usually mild and cardiovascular manifestations, such as tachycardia and wide pulse pressure, are often the only indication of hyperthyroidism. Eye signs, neuromuscular features, and gastrointestinal symptoms are usually absent, in contrast to their association with Graves' disease.

The incidence of association of hyperthyroidism with hyperfunctioning thyroid nodule seems high in children, as compared to adults. Eight of the 11 children with this disorder were found to be hyperthyroid, as shown in Table 2, whereas collating five series gives an incidence of hyperthyroidism

of 48% in a total of 123 cases of hyperfunctioning thyroid nodules in adult patients.[9-13]

Note that all of the children listed in Table 2 are girls. This indicates a definite predominance in girls as well as in women.[7,9,12] Although pathologic examinations of thyroid nodules reveal adenoma in the majority of adult patients,[9] adenoma is much less frequently identified in children, as demonstrated in Table 2.

Regarding thyroid function in adult patients with hyperfunctioning thyroid nodules, considerable information is available in the literature.[7-9,11-13] Thyroid function studies in children are given in Table 1.

Patients with clinical features of hyperthyroidism usually show significant elevations in serum T_3 and T_4 concentrations. A preferential elevation of serum T_3 (T_3-toxicosis) also often occurs. In addition, serum TSH usually fails to respond to TRH stimulation and the thyroidal ^{131}I uptake is not suppressible by exogenous administration of thyroid hormone, regardless of whether the patient is euthyroid or hyperthyroid. Although the positive correlation between the size of thyroid nodule and the presence of hyperthyroidism has been reported in adult patients,[9,12] such a correlation is not found in children.

Since the patients present most frequently with a thyroid mass or a swelling in the neck, the differential diagnosis includes acute suppurative thyroiditis, subacute thyroiditis, Hashimoto's thyroiditis, thyroid carcinoma, thyroid cyst, benign adenoma, and thyroid dysgenesis.

The physical examination of the thyroid gland and surrounding lymph nodes, thyroid function studies and the thyroid scan may be sufficient for diagnosis. Among these, the thyroid scan is especially useful as a diagnostic tool. The thyroid scintigram always demonstrates a hot nodule with no visible uptake in the remainder of the thyroid. It is of importance to remember that although function in a thyroid nodule largely excludes a malignant disease, there have been some reports of carcinoma in hyperfunctioning thyroid nodules[5,14,15] and that 3% to 4% of the patients with Hashimoto's thyroiditis have functioning nodules.[16] The hemiagenesis of the thyroid gland may simulate a unilaterally functioning nodule.[5]

Treatment consists of surgical removal of the nodule if the patient is hyperthyroid or if there are some clinical findings suggestive of thyroid carcinoma, such as (1) rapid growth of the nodules, (2) enlargement of adjacent lymph nodes, (3) hoarseness or vocal cord paralysis, (4) rock-like hardness, and (5) history of prior radiation therapy to the neck.

Antithyroid drug therapy is considered only for short-term management. If the patient remains euthyroid, follow-up may be desirable. Studies of the natural history of hyperfunctioning thyroid nodule indicate a rare progression to thyrotoxicosis, but not to malignancy.[11,12,17]

Cecile A. Gadzala, RN; Jacqueline Stringer, PhD; Winston R. Maxted, PhD

• Two premature infants in a special care nursery acquired late-onset group B streptococcal (GBS) sepsis within a 24-hour period. The infecting strains were serotype III organisms with bacteriophage type 7/11/12. Cultures of the mothers of the two affected infants were negative for GBS, implying nosocomial acquisition of infection. Although 32% of nursery personnel had mucosal carriage of GBS, none of the seven isolates of GBS type III was the same bacteriophage type as the two infecting strains. Of the other infants hospitalized in the nursery, five were asymptomatically colonized with GBS. These infants were in bassinets adjacent to the affected infants; all five of their isolates were identical to the two infecting strains. We conclude that infant-to-infant transmission may result in nosocomial late-onset GBS septicemia.

(*Am J Dis Child* 134:964-966, 1980)

Vertical transmission from the maternal genital tract during labor is recognized as the principal mode of perinatal acquisition of group B streptococci (GBS). However, only about 1% of infants born to colonized mothers manifest "early-onset" septicemia.[1] The association of early-onset invasive disease with perinatal complications[2] and diffuse pneumonia[3] support the concept of intrapartum amniotic fluid infection as a major pathogenic determinant. In contrast, the transmission and pathogenetic mechanisms of "late-onset" GBS septicemia have not been defined. Late-onset disease could result from postnatal colonization by GBS strains of nonmaternal origin, a hypothesis that has drawn attention to the phenomenon of nosocomial colonization in the neonatal nursery setting.

In several recent reports of hospital-acquired GBS colonization of normal newborns,[4-6] personnel with mucosal carriage have been identified as a major reservoir. However, owing to difficulties in exact identification of GBS strains, it has not been possible to document the epidemiologic significance of this reservoir, nor the contribution of horizontal transmission from infant to infant.

The simultaneous occurrence of late-onset GBS sepsis in two hospitalized premature infants offered a rare opportunity to study the mode of transmission of this condition. In the investigation, we used serotyping, antibiotic susceptibility testing, assay of extracellular neuraminidase, and bacteriophage typing to "fingerprint" GBS strains from the two affected infants and from other colonized infants and personnel.

PATIENTS AND METHODS

On Nov 26 and 27, 1978, within a 24-hour period, two premature infants in the Michael Reese Hospital Special Care Nursery, Chicago, experienced late-onset GBS septicemia. Lethargy and apneic spells were initial symptoms in the two affected infants. They were aged 11 and 71 days and had both been hospitalized in the unit since birth. Neither infant had meningitis; both responded promptly to initial therapy with ampicillin sodium and kanamycin sulfate followed by a ten-day course of aqueous penicillin G. Blood cultures from the two infants yielded GBS serotype III.

Both infants were being cared for in open cribs in the "intermediate care" room of the nursery, along with 16 other infants. An additional ten infants were hospitalized in the adjacent "intensive care" room of the nursery.

Throat, ear, umbilical, and rectal swabs were obtained from all infants in the intermediate- and high-risk areas on Dec 7, 1978. Swabs were inoculated directly into selective broth[8] and were subcultured after overnight incubation to sheep blood agar plates. Colonies were identified as GBS by means of the Christie, Atkins, and Munch-Petersen (CAMP) reaction[9] and serotyped

by capillary precipitation.[10] Using the same techniques, three previous culture surveys of all hospitalized neonates had been conducted in the nursery on May 18, June 26, and Oct 20, 1978. Two subsequent surveys were also carried out on Jan 9 and Feb 12, 1979.

Cultures of throat, vagina, and rectum for GBS were obtained from the mothers of all infected and colonized infants identified in the Dec 7 survey. Fifty-three of the 67 nurses and physicians working in the nursery at the time of the two late-onset cases were also surveyed for GBS carriage, including the 20 personnel who had cared for the two infected infants during the week prior to their onset of illness. Throat, vaginal, and rectal cultures were obtained from female personnel; throat and rectal swabs were obtained from male personnel.

Isolates of GBS type III were further characterized by antibiotic sensitivity patterns, neuraminidase production, and bacteriophage type. Sensitivity to erythromycin and tetracycline[11] were determined by the Kirby-Bauer technique. Extracellular neuraminidase production was assayed by the method of Milligan et al.[12] Bacteriophage typing was based on patterns of bacterial lysis by a battery of 31 streptococcal bacteriophages, as recently described by Stringer.[13]

RESULTS

The GBS type III isolates from the two infants with late-onset sepsis were sensitive to erythromycin and tetracycline, did not produce neuraminidase, and were both of phage type 7/11/12. Both sets of maternal cultures were negative for GBS, as was a set of cultures from the older of the two infants obtained in the Oct 20 survey. The identity of the two strains, the close temporal relationship of illness onsets, and the negative maternal and prior infant cultures were consistent with nosocomially acquired infection.

Culture surveys in the two areas of the nursery are summarized in the Table. In the three surveys conducted prior to the case cluster, no GBS colonization was detected in hospitalized infants. In addition to the two affected infants, the survey conducted on Dec 7, 1978, disclosed five other neonates with asymptomatic GBS colonization. Of the seven infants, throat cultures were positive in five, rectal cultures were positive in five, and ear and umbilical cultures were all negative. The five GBS isolates from asymptomatic infants were identical in serotype, erythromycin and tetracycline sensitivity, absent neuraminidase production, and bacteriophage type to those from the infected babies. The five colonized infants were of low birth weight and were located in bassinets adjacent to the two infected infants in the intermediate-care area. The group included one single birth, one of a pair of twins, and all three of a set of triplets. None was receiving "banked" breast milk feedings. Cultures from the mothers of these infants were negative for GBS, although the mother of the set of triplets had received ampicillin for postpartum fever at another hospital prior to our cultures. Subsequent culture surveys of infants hospitalized in the nursery revealed prevalences of GBS in five of 23 on Jan 9 and in one of 29 on Feb 12, 1979. The bacteriophage type 7/11/12 serotype III strain was not isolated in these surveys, although four of the five Jan 9 isolates were serotype III strains of bacteriophage type 12.

Group B Streptococcus Culture Surveys of Special-Care-Nursery Infants

*GBS indicates group B streptococcus.
†All GBS type III tetracycline-sensitive (S) erythromycin-S neuraminidase (—); phage 7/11/12.
‡One GBS type III tetracycline-S erythromycin-S neuraminidase (+); phage 12.
§Three GBS type III tetracycline-S erythromycin-S neuraminidase (+); phage 12; one GBS type III tetracycline-S erythromycin-S neuraminidase (+); phage 27/31.
‖One GBS type Ia tetracycline-S erythromycin-S neuraminidase (—); phage not done.

The culture survey of nursery personnel conducted at the time of the two index cases revealed an overall prevalence of GBS colonization of 34%. Of the 18 colonized personnel, rectal swabs were positive in 16; vaginal swabs in 13; and throat swabs in 3. A variety of GBS serotypes were isolated (3 GBS Ia, 3 GBS Ib, 5 GBS II, and 7 GBS III). None of the seven GBS type III isolates from personnel was identical to the strain isolated from the infants with late-onset sepsis. Three of these isolates were bacteriophage type 12, one was type 11/12/27/31, and three were nontypable.

COMMENT

Our findings suggest that infant-to-infant transmission of late-onset GBS infection may occur in a special-care-nursery setting. Vertical transmission did not appear to account for the two cases observed, since both mothers had negative cultures for GBS. Transmission from nursery personnel with mucosal carriage was not documented. Although 34% of personnel were colonized with GBS, none carried the bacteriophage type 7/11/12 serotype III strain responsible for the two late-onset cases. On the other hand, all five colonized infants in the nursery were found to be carrying the identical strain. The origin of this organism and the actual means of transmission from infant to infant remain speculative. The three colonized triplets, transferred from another hospital four days prior to the onset of illness in the index cases, may have introduced the organism to the nursery. Transient carriage of GBS on the hands of personnel is the likely means of transmission between infants.

In previous studies of nosocomially acquired GBS colonization in full-term infants, 41% to 52% of those colonized were born to women with negative vaginal and/or throat cultures.[5-7] Although nursery personnel in these studies had higher rates of colonization than mothers or personnel from

other hospital areas, the investigators were cautious about interpreting this to mean that personnel carriers were an important source of nosocomial infant colonization. In fact, based on differences in serotype distribution among personnel and infants, Paredes et al[6] hypothesized that infant-to-infant cross infection was the predominant mechanism. Anthony et al,[7] using bacteriophage typing techniques, have recently demonstrated this mechanism of GBS transmission within cohorts of infants in a Los Angeles hospital, and showed that a colonized mother served as the common source for the particular strain in each cohort. In the present study, a common source was not identified, although the mother of the triplets might be incriminated. Our data rule against nursery personnel as a reservoir for the infecting strain.

Propagation from infant to infant also has been incriminated in most investigations of group A streptococcal nursery outbreaks.[14-16] Infants with subclinical omphalitis often serve as the reservoir of group A organisms, and local antimicrobial treatment of the umbilical cord, combined with systemic penicillin prophylaxis, has been required to terminate smouldering epidemics. In contrast, the GBS strain responsible for the present cases was not isolated from umbilical cultures and disappeared from the nursery without imposition of control measures. On the whole, we found asymptomatic infant GBS colonization to be relatively uncommon among the babies in this high-risk population. This may reflect frequent antibiotic use, and is similar to the findings of Sprunt et al[17] in a comparable setting.

A combined approach to "fingerprinting" of GBS strains by serotype and bacteriophage type appears to be a useful means of studying patterns of acquisition of these organisms. In our experience, antibiograms and neuraminidase production were less discriminating. Although comparable data are not as yet available in the United States, bacteriophage type 7/11/12 has been relatively rare in the United Kingdom, accounting for less than 1% of serotype III isolates.[13] The bacteriophage type 12 serotype III strain encountered among personnel and in infants during our Jan 9 survey appears to be a more common organism, and thus its epidemiologic significance remains uncertain.

This study was supported in part by Public Health Service grant RO-1-HD-09700 from the National Institute of Child Health and Human Development.

John B. Paton, MD, provided assistance in the culture surveys. Peggy Kelly and Madeline Murphy provided technical assistance.

Human Toxocariasis in a Rural Community

Wesley E. Jones, MD; Peter M. Schantz, VMD, PhD; Kate Foreman, RN; Linda Kay Smith, RN; Ernest J. Witte, VMD, MPH; David E. Schooley, DO; Dennis D. Juranek, DVM, MSc

• A questionnaire and serologic survey of a Pennsylvania community revealed that 23 (54%) of 43 study participants had antibody titers to *Toxocara canis* (enzyme-linked immunosorbent assay test [ELISA]) in the range defined as positive (≥ 1:32). Age-specific seropositivity rates were highest among adults (≥ 18 years). Positive titers ranged from 1:32 to 1:512. Seropositivity did not cluster by family, and seropositivity rates were significantly higher than those of a control group. Physical examination and laboratory tests designed to detect clinical signs of toxocariasis were performed on individuals with positive ELISA titers. Nine of 23 had a history of pica, seizures, or chronic pulmonary symptoms; however, physical examination revealed no abnormalities. Although medical examination and laboratory tests revealed a few abnormalities, neither the visceral larva migrans syndrome nor the ocular lesions characteristic of those produced by *Toxocara* sp were observed in any individual. We conclude that although certain populations may have high seropositivity rates to *Toxocara* antigens, indicating previous infection, clinical disease may be uncommon.

(*Am J Dis Child* 134:967-969, 1980)

The larvae of *Toxocara* sp, the common roundworms of dogs and cats, are capable of infecting human beings who ingest eggs containing infective-stage larvae.[1,2] The prevalence and distribution of human infection have remained unknown because of the nonspecific nature of the signs and symptoms and the lack of a reliable serologic test to establish the diagnosis. Recently, however, the enzyme-linked immunosorbent assay (ELISA) has been shown to give highly satisfactory results in terms of sensitivity and specificity,[3-6] and the test appears suitable for clinical and epidemiologic studies of zoonotic toxocariasis. We report the results of a clinical and serologic examination of a community with a high rate of endemic toxocariasis.

BACKGROUND

In June 1977, the Center for Disease Control (CDC), Atlanta, was contacted by the Bureau of Children's Services, Pennsylvania State Department of Health, regarding several suspect cases of visceral larva migrans in a community. Three siblings (aged 3 to 6 years) had antibody titers to *Toxocara* sp (ELISA test) in the range defined as positive (≥ 1:32) by workers at the University of Pittsburgh, where the test was developed.[3] Lesser but measurable titers were obtained on serum specimens from the three remaining household members. In addition, five of the six members had eosinophilia. Of nine additional samples from individuals living in the same community, six demonstrated detectable antibody to *Toxocara*; therefore, an investigation was initiated.

The community is located in the Appalachian mountains of southern Pennsylvania where 70 to 100 persons live in trailers and two- and three-room houses. Most families have poorly maintained toilet facilities (privies) and obtain water from a few "springs," which are centrally located. There is no organized garbage collection, and animals, especially dogs, roam freely through the yards. The absence of paved roads or walks allows large amounts of mud, possibly containing animal excreta, to be carried indoors.

METHODS

Visits were made to all the homes and the purposes of the investigation were explained. Volunteers who consented to participate were questioned about length of residence and dog ownership and were requested to provide a blood and stool specimen. Control subjects of similar age, sex, and race were selected from a clinic population in a nearby community. In contrast to the study group, all control subjects obtained water from properly maintained wells, and had adequate toilet facilities and restricted yards. The sera were tested at CDC with use of the toxocaral ELISA test.[3,4] Stool specimens were preserved in two vials (one containing 5% formaldehyde solution and the other polyvinyl alcohol) and examined at CDC with use of direct mounts and formal-ether concentration techniques. Individuals from both study and control groups found to have positive ELISA titers were evaluated by physical examination, including ophthalmologic examination, laboratory tests (prothrombin time, hematocrit reading, WBC count and differential cell count, immunoglobulin level, and isohemagglutinin titers). Soil samples from various areas in the community were collected and examined with a formal-ether concentration. Water samples were collected from three springs in the study community and tested for total coliforms by the Pennsylvania Department of Environmental Resources.

RESULTS

Forty-three residents from 13 families comprised the study group. Of these, 23 (54%) were seropositive by the ELISA test at a titer of ≥ 1:32 (range, 1:32 to 1:512). In the control population, a positive ELISA titer (range, 1:32 to 1:128) was found in four (9%) of 44 individuals from 25 families. The seropositivity rate of the study group was significantly higher than that of the control group ($P < .001$, Fisher's exact test). Rates

increased with age in the study group, but age association was not apparent among control subjects (Table 1). There were no significant differences in seropositivity rates between male and female subjects in either group. The length of residence for study group participants ranged from 3 months to 11 years. No differences were found between seropositive and seronegative participants with respect to length of residence. Seropositive persons did not cluster by family in the study group but were distributed throughout ten of the 13 participating families (Table 2). Each of the four individuals with positive titers in the control group was from a different family.

Nine (69%) of the 13 families in the study group owned dogs, and four families (31%) did not (including the two families with no persons having positive titers). In the control group, 14 (56%) of 25 families owned dogs. Three of the seropositive control individuals were from families that owned dogs. These differences were not statistically significant ($P > .05$). In both study and control groups, all families that owned dogs had obtained them as puppies.

In the study group, stool specimens were submitted by 14 persons representing six households. Parasites were demonstrated in seven specimens (*Ascaris lumbricoides* in three, *Giardia lamblia* in three, and *Chilomastix mesnili* in one). Stool specimens were submitted by 11 persons in the control group, and two of these were positive for *G lamblia*. Two of four surface soil samples collected from areas frequented by dogs were positive for *Toxocara* ova. Water samples collected from three separate sources in the involved community and tested for total coliform count were found to be grossly contaminated.

A history was taken and a physical examination was performed on 23 persons who had positive ELISA titers. Two persons reported a history of seizures (at age 3 and 10 years) in the past, and one (aged 47) had hepatomegaly associated with congestive heart failure on physical examination. Laboratory studies showed an anemia in nine of 22 individuals (age adjusted) with a mean hemoglobin level of 12.2 gm/dL and a ≥ 5% eosinophilia in nine of 22 individuals with a mean eosinophilia of 5.59%. Determinations of prothrombin time, immunoglobulin levels, and isohemagglutinin titers were also made (Table 3).

The ELISA tests were repeated after one year for a group of 23 seropositive and seronegative individuals. Only in four specimens did the titers differ from earlier results by more than two dilutions. For three of these, the titers decreased (1:128 to 1:4, 1:8 to 0, and 1:32 to 1:4), and for one the titer rose (1:2 to 1:128).

COMMENT

More than half of the persons tested in this community, both adults and children, had serologic evidence of toxocariasis; this is a much higher seroprevalence than observed in other communities. Samples of some other populations have had a toxocaral seroprevalence that varied between 0% and 13%, depending on age, geographic region, and income levels.[7] The toxocaral ELISA test has been extensively evaluated[3,6] and has been shown to be both specific and sensitive for toxocariasis. False-positive reactions caused by the presence of heterophil

antibody, C-reactive protein, or antibodies to the parasites are eliminated by previous absorption of the test serum with ascarid antigens.[3] At a diagnostic titer of 1:32, the diagnostic sensitivity was approximately 75% and the specificity was greater than 90%.[4,6] The apparent 10% nonspecificity in clinical evaluations appears to be a result of the prevalence of asymptomatic infection.

Larvae of *Toxocara* sp can invade almost any tissue of the human body. Most cases are probably subclinical, but two well-known forms of clinical expression of toxocariasis exist: one, visceral and the other, ocular.[7-9] The visceral larva migrans (VLM) syndrome occurs most frequently in children 1 to 5 years of age and is characterized by coughing or wheezing, transitory pulmonary infiltration, hepatomegaly or splenomegaly, leukocytosis, persistent eosinophilia, elevated anti-A or anti-B isohemagglutinin levels, increased immunoglobulin concentrations, and a history of pica.[7,10] Its association with pica suggests that clinical illness may be a function of the numbers of eggs ingested, frequency of reinfection, or other, as yet undefined, factors. Larval invasion of the eye is not uncommon, and the characteristic lesion is a retinal granuloma.[11,12] Ocular disease is usually seen in patients who have no other signs or symptoms of VLM, either concurrently or historically.[7-9] We were unable to find evidence of the VLM syndrome or ocular lesions characteristic of toxocaral disease at the time we performed medical examinations on seropositive persons. These negative findings support the concept derived from clinical and experimental observations that most infections caused by *Toxocara* sp are subclinical. Although some of our study population had a history of medical problems compatible with a diagnosis of VLM (seizures, pulmonary complaints, etc) these were too nonspecific to permit conclusions regarding cause.

In the past, investigators have found that children in the 0- to 4-year age range are most likely to come into contact with infective *Toxocara* eggs, and, because of a generally lower level of hygiene, are most likely to become heavily infected and manifest clinical illness. The exact mechanism of spread in this population was not determined; however, of interest is the large percentage of seropositive adults.

One possible explanation for this finding is that a positive titer does not reflect recent infection but represents persistence of antibody from an earlier infection. Thus, the seropositive adults presently living in this community could have been exposed to infection earlier in life while living in a similar environment in a different community. This would explain the lack of a statistical correlation between seropositivity and length of residence. Although this phenomenon has not been demonstrated in humans, animal studies have shown that *Toxocara* larvae may remain alive in the tissues of rhesus monkeys for ten or more years. More recently, one of us (P.M.S., unpublished data) has demonstrated that toxocaral antibody is detectable by the ELISA test at high titers in the serum of monkeys for greater than 30 months after experimental infection. Another possibility that cannot be excluded is that adults living under the conditions existing in this community may be at higher risk of infection and may have acquired infection recently.

Studies on the prevalence of *T canis* in dogs in the United States revealed that 20% to 21% of adult dogs and as many as 98% of puppies may be infected.[7,13,14] If we assume this to be an accurate reflection of the nationwide prevalence of this parasite, then a combination of dogs allowed to defecate in areas of human habitation and a generally low level of personal hygiene make an ideal setting for transmission of *Toxocara* sp to humans. Indeed, the most likely source of infection in this community is the large population of dogs that roam freely through the area.

This community was not representative of the general US population, either rural or urban. Rather, it was characterized by a generally low level of hygiene and sanitation. We conclude that although clinical disease is uncommon, infection with *T canis* may be more widespread than previously indicated. A greater understanding of the epidemiologic factors and the methods required to control or prevent this zoonosis is needed.

You can help the ADD* child with Cylert

(pemoline)

Day-long behavior therapy without dosing problems at school

Impressive all-day control.

Cylert works extremely well, given an adequate period of trial. Single daily doses are as effective for behavior control as multiple doses of methylphenidate or amphetamines. Blood levels are well sustained, without necessity for multidose administration.

No troublesome midday dose.

Cylert avoids problems of taking a drug at school. No involvement of school personnel. No peer teasing about noon-time dosing. The parents manage all medication, and the child carries no drugs. (And note that Cylert is Schedule IV, not II.)

Cylert® (pemoline) C IV

18.75, 37.5, 75 mg tablets; 37.5 mg chewables

Just once a day. At home.

*ADD: Attention Deficit Disorder (formerly called MBD, Minimal Brain Dysfunction), or the Hyperkinetic Syndrome. Please see next page for Brief Summary.

ABBOTT

Cylert® (pemoline)

DESCRIPTION: CYLERT (pemoline) is a central nervous system stimulant. Pemoline is structurally dissimilar to the amphetamines and methylphenidate.

It is an oxazolidine compound and is chemically identified as 2-amino-5-phenyl-2-oxazolin-4-one.

Pemoline is a white, tasteless, odorless powder, relatively insoluble (less than 1 mg./ml.) in water, chloroform, ether, acetone, and benzene; its solubility in 95% ethyl alcohol is 2.2 mg./ml.

CYLERT (pemoline) is supplied as tablets for oral administration.

CLINICAL PHARMACOLOGY: CYLERT (pemoline) has a pharmacological activity similar to that of other known central nervous system stimulants; however, it has minimal sympathomimetic effects. Although studies indicate that pemoline may act in animals through dopaminergic mechanisms, the exact mechanism and site of action of the drug in man is not known.

There is neither specific evidence which clearly establishes the mechanism whereby CYLERT produces its mental and behavioral effects in children, nor conclusive evidence regarding how these effects relate to the condition of the central nervous system.

The serum half-life of pemoline is approximately 12 hours. Peak serum levels of the drug occur within 2 to 4 hours after ingestion of a single dose. Multiple dose studies in adults at several dose levels indicate that steady state is reached in approximately 2 to 3 days.

Metabolites of pemoline include pemoline conjugate, pemoline dione, mandelic acid, and unidentified polar compounds. CYLERT is excreted primarily by the kidneys; approximately 75% of an oral dose is recovered in the urine within 24 hours. Approximately 43% of pemoline is excreted unchanged.

CYLERT (pemoline) has a gradual onset of action. Using the recommended schedule of dosage titration, significant clinical benefit may not be evident until the third or fourth week of drug administration.

INDICATIONS: CYLERT is indicated as an integral part of a total treatment program which typically includes other remedial measures (psychological, educational, social) for a stabilizing effect in children with a behavioral syndrome characterized by the following group of developmentally inappropriate symptoms: moderate to severe distractibility, short attention span, hyperactivity, emotional lability, and impulsivity. The diagnosis of this syndrome should not be made with finality when these symptoms are only of comparatively recent origin. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of central nervous system dysfunction may or may not be warranted.

Attention Deficit Disorder and Hyperkinetic Syndrome are among the terms being used to describe the above signs and symptoms. In the past, a variety of terms has been associated with these signs and symptoms, including: Minimal Brain Dysfunction, Hyperkinetic Reaction of Childhood, Hyperkinetic Syndrome, Hyperactive Child Syndrome, Minimal Brain Damage, Minimal Cerebral Dysfunction, and Minor Cerebral Dysfunction.

CONTRAINDICATIONS: CYLERT (pemoline) is contraindicated in patients with known hypersensitivity or idiosyncrasy to the drug. (See ADVERSE REACTIONS.)

WARNINGS: CYLERT is not recommended for children less than 6 years of age since its safety and efficacy in this age group have not been established.

Clinical experience suggests that in psychotic children, administration of CYLERT may exacerbate symptoms of behavior disturbance and thought disorder.

Data are inadequate to determine whether chronic administration of CYLERT may be associated with growth inhibition; therefore, growth should be monitored during treatment.

PRECAUTIONS: Drug treatment is not indicated in all cases of the behavioral syndrome characterized by moderate to severe distractibility, short attention span, hyperactivity, emotional lability and impulsivity. It should be considered only in light of the complete history and evaluation of the child. The decision to prescribe CYLERT should depend on the physician's assessment of the chronicity and severity of the child's symptoms and their appropriateness for his/her age. Prescription should not depend solely on the presence of one or more of the behavioral characteristics.

When these symptoms are associated with acute stress reactions, treatment with CYLERT is usually not indicated.

Long-term effects of CYLERT in children have not been well established.

Liver function tests should be performed prior to and periodically during therapy with CYLERT. The drug should be discontinued if abnormalities are revealed and confirmed by follow-up tests. (See ADVERSE REACTIONS regarding reports of abnormal liver function tests and jaundice.)

CYLERT should be administered with caution to patients with significantly impaired hepatic or renal function.

The interaction of CYLERT with other drugs has not been studied in humans. Patients who are receiving CYLERT concurrently with other drugs, especially drugs with CNS activity, should be monitored carefully.

CYLERT failed to demonstrate a potential for self-administration in primates. However, the pharmacologic similarity of pemoline to other psychostimulants with known dependence liability suggests that psychological and/or physical dependence might also occur with CYLERT. There have been isolated reports of transient psychotic symptoms occurring in adults following the long-term misuse of excessive oral doses of pemoline. CYLERT should be given with caution to emotionally unstable patients who may increase the dosage on their own initiative.

Usage during Pregnancy and Lactation: The safety of CYLERT (pemoline) for use during pregnancy and lactation has not been established.

Studies in rats have shown an increased incidence of stillbirths and cannibalization when pemoline was administered at a dose of 37.5 mg./kg./day. Postnatal survival of offspring was reduced at doses of 18.75 and 37.5 mg./kg./day.

ADVERSE REACTIONS: Insomnia is the most frequently reported side effect of CYLERT; it usually occurs early in therapy, prior to an optimum therapeutic response. In the majority of cases it is transient in nature or responds to a reduction in dosage.

Anorexia with weight loss may occur during the first weeks of therapy. In the majority of cases it is transient in nature; weight gain usually resumes within three to six months.

Stomach ache, skin rashes, increased irritability, mild depression, nausea, dizziness, headache, drowsiness, and hallucinations have been reported.

Elevations of SGOT, SGPT, and serum LDH have occurred in patients taking CYLERT, usually after several months of therapy. These effects appear to be reversible upon withdrawal of the drug, and are thought to be manifestations of a delayed hypersensitivity reaction. There have also been a few reports of jaundice occurring in patients taking CYLERT; a causal relationship between the drug and this clinical finding has not been established.

The following CNS effects have been reported with the use of CYLERT: dyskinetic movements of the tongue, lips, face and extremities; nystagmus and nystagmoid eye movements; and convulsive seizures. A definite causal relationship between CYLERT and these reactions has not been established.

Mild adverse reactions appearing early during the course of treatment with CYLERT often remit with continuing therapy. If adverse reactions are of a significant or protracted nature, dosage should be reduced or the drug discontinued.

OVERDOSAGE: Signs and symptoms of acute CYLERT overdosage may include agitation, restlessness, hallucinations, dyskinetic movements and tachycardia. The treatment for an acute overdosage of pemoline is essentially the same as that for an overdosage of any CNS stimulant. Management is primarily symptomatic and may include induction of emesis or gastric lavage, sedation, and other appropriate supportive measures.

Results of studies in dogs indicate that extracorporeal hemodialysis may be useful in the management of CYLERT overdosage; forced diuresis and peritoneal dialysis appear to be of little value.

DOSAGE AND ADMINISTRATION: CYLERT (pemoline) is administered as a single oral dose each morning. The recommended starting dose is 37.5 mg./day. This daily dose should be gradually increased by 18.75 mg. at one week intervals until the desired clinical response is obtained. The effective daily dose for most patients will range from 56.25 to 75 mg. The maximum recommended daily dose of pemoline is 112.5 mg.

Clinical improvement with CYLERT is gradual. Using the recommended schedule of dosage titration, significant benefit may not be evident until the third or fourth week of drug administration.

Where possible, drug administration should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued therapy.

Review

Food Sensitivity

A Critical Review and Practical Approach

S. Allan Bock, MD

One of the most common problems brought to the attention of today's pediatrician is the question of a possible association between ingestion of a particular food and symptoms experienced by a child. Publications to which parents have ready access, including newspapers, are replete with reports of various adverse reactions to foods in children (commonly called "allergy"). Because the pediatrician is considered by parents to be an authority on health matters, he is often requested to comment on reports that parents have read. This is a difficult task because often the reports are based on comments made at meetings that are not available in print for the pediatrician to analyze critically. Even if there is a written report, it may be difficult for the pediatrician to spend the time required to help parents become critical readers of lay publications.

This review considers the topic of food sensitivity, including the basic principles and the clinical approach. A step-by-step procedure is outlined in a later section for those physicians who desire to take the time to evaluate their own patients for food sensitivity. Details not included in this review may be found in articles in specialty publications.[1,2] It is hoped that a critical evaluation of this subject will aid pediatricians in their daily interaction with patients who are concerned with this subject.

From the National Jewish Hospital and Research Center, and the University of Colorado Health Sciences Center, Denver.

Reprint requests to Department of Pediatrics, National Jewish Hospital and Research Center, 3800 E Colfax Ave, Denver, CO 80206 (Dr Bock).

The term "food sensitivity" has been adopted and the term "food allergy" abandoned because the latter has been misused by application to a multitude of anecdotally reported syndromes that have not been shown to be associated with immunologic interactions. This review will be primarily limited to a discussion of those reactions that do have associated immunologic laboratory findings. However, because pediatricians are so commonly queried about other syndromes, comments will be offered about these conditions at the end of this review.

IMMUNOLOGIC PRINCIPLES

Antigen Sensitization

Though this review is not meant to be an exhaustive discussion of immunology, certain fundamentals need to be considered in order to understand the practical approach developed in a later section. When antigen is ingested, initially it must be processed and presented to immunologically competent cells so that sensitization may occur or a reaction appear in a sensitized person. Antigen reaches immunocompetent cells via the mucosa (either respiratory or gastrointestinal [GI], which have a common embryologic origin), through the skin, or perhaps by crossing the placenta in the fetus. Very little is known in humans concerning which molecular antigens can cross the placenta; however, it is well known that the fetus produces immunoglobulins. Premature infants have been shown to produce antibodies to bovine serum albumin.[3] The form in which most food proteins cross the mucosal barrier is also incompletely understood, but it is obvious that antigenic determinants of proteins and perhaps relatively intact proteins themselves do cross the mucosa, with the result that all infants with a normal immune system make antibodies to foods in their diet, especially to milk[4,5] (and from written communication of C. D. May, MD, S. J. Fomon, MD, and L. Remigio, 1980).

Antigens (both food and microbial) first encounter the immune system at the mucosal surface and in the lumen. These reactions have not been well elucidated in humans for food antigens, but there are animal models that suggest an investigative approach to be pursued in humans.[6,7]

When food antigens cross the GI mucosa, they first encounter immunologically reactive cells in the lamina propria. Most of these are plasma cells of which the largest number are producing IgA. It has been shown in humans that sensitized mast cells may also be encountered in the intestine, and if activated they will degranulate.[8] Antigens gain access to Peyer's patches through "specialized M cells."[9] The stimulation of Peyer's patch lymphocytes and the resulting circulation of these cells through the lymphatic system with subsequent homing of the lymphocytes to the lamina propria is an area of active investigation, which when unraveled should aid our understanding of immunologic events in the intestine. Proteins or fragments thereof reach the circulation with enough antigenicity to stimulate clinically apparent reactions at sites distant from the point of absorption.

Antigen-Antibody Interaction

When antigen encounters sensitized cells, a sequence of immunologic reactions occurs that must be carried to completion for clinical symptoms to be manifested (Fig 1). The presence of specific antibodies (sensitization) is not synonymous with symptoms, and the difference will be discussed in detail in a subsequent section. Antigen-antibody interaction can lead to lymphocyte proliferation, direct cytotoxicity, or release of numerous mediators. These cells or their mediators then interact with end organs; this may then result in clinically observable symptoms.

Each step in this sequence is governed by a stimulus-response relationship that must

be satisfied before the next step may occur (Fig 2). If the relationship is not satisfied at each step, ie, if a certain threshold for reaction is not exceeded, then the next step will not occur and no clinically apparent symptoms will be observed. Thus, it should not be surprising to learn that a child has antibodies to one or more proteins yet exposure by the usual routes does not result in symptoms.

CLINICAL PRINCIPLES

Definition of Terms

One of the most troublesome aspects of the subject of food sensitivity is misuse of the term "allergy." This term will not be used here; instead, the term food sensitivity will be used to avoid some of the confusion. The dilemma has arisen because the term allergy has two components, namely, sensitization (the presence of antibodies) and the presence of symptoms. These are easily confused for one another when the considerations discussed earlier are forgotten. When patients describe reactions to foods and suggest that they are due to allergy, the patients should be encouraged to use the term adverse reaction to food until the symptoms have been objectively confirmed and the mechanism has been identified.

The terms "symptomatic sensitivity" and "asymptomatic sensitivity" are much more useful than the term food allergy when considering immunologically mediated adverse reactions to food. Symptomatic sensitivity indicates that sensitization has been demonstrated, the adverse reaction has been objectively confirmed, and other causes of reaction have been eliminated. Asymptomatic sensitivity means that sensitization has been demonstrated, but the patient is able to tolerate the food when it is consumed as part of the diet in usual portions prepared by customary means.

Differential Diagnosis

It is not the purpose of this review to discuss in detail the differential diagnosis of adverse reactions to foods; however, it must be remembered that immunologic reactions are not the only cause. Enzyme deficiencies, particularly lactose deficiency, are well known to all pediatricians. Less common enzyme deficiencies such as galactosemia will need to be considered in infants as possible causes of adverse reactions to foods. Toxins in foods (eg, aflatoxins), while not common, may be an occasional cause of symptoms and must be considered. There are both natural toxins and contaminants that may be products of modern living.[10] Examples of natural constituents are alkaloids, as found in mushrooms; hemagglutinins, as found in beans; goitrogens, as found in cabbage; cyanide, as found in the stones of fruits; pressor amines, as found in bananas; and oxalates, as found in rhubarb. Examples of contaminants are saxitoxins, ergot, aflatoxins, penicillin, mercury, and pesticides. Additives, such as dyes and nitrites, must also be considered.

In addition, there may be as yet unidentified biochemical reactions in the intestine or elsewhere in the body that are initiated by ingested substances but have no immunological reactions associated with them. The confirmation of this conjecture must await further investigation.

Beliefs about reactions to foods greatly influence the outcome of food challenges. As will be shown later, many reactions to foods, which are plausibly described by reasonable parents, simply cannot be confirmed objectively. The final category of adverse reactions to foods are immunological reactions, and the remainder of this review will be devoted to the interaction of foods and components of the immune system.

MANIFESTATIONS OF FOOD SENSITIVITY REACTIONS

Reaginic Reactions

Most reviews of foods sensitivity divide the reactions into various syndromes or constellations of symptoms. It would seem more helpful to attempt to divide these reactions by the mechanism that can be shown to be associated or is under investigation. Therefore, the following scheme has

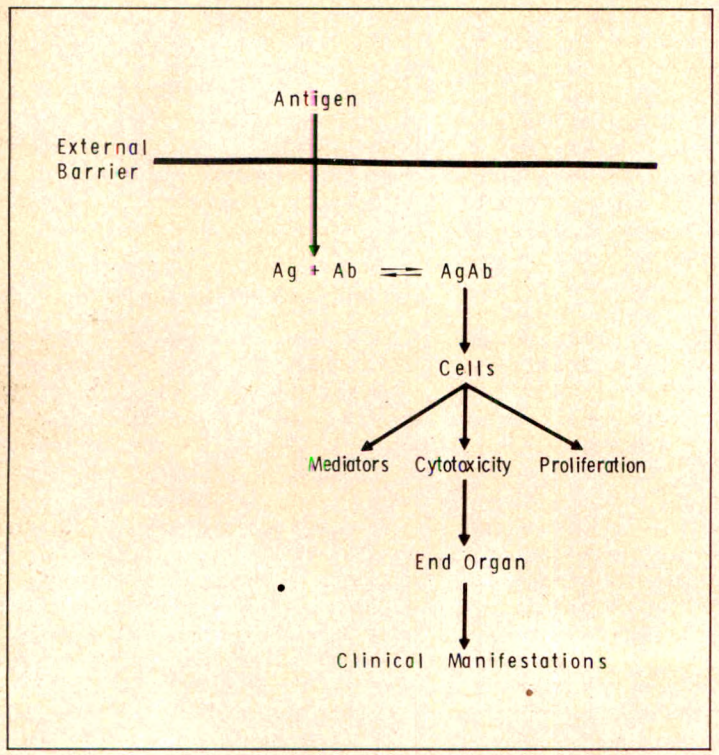

Fig 1.—Immunologic events after exposure of a sensitized person to antigen.

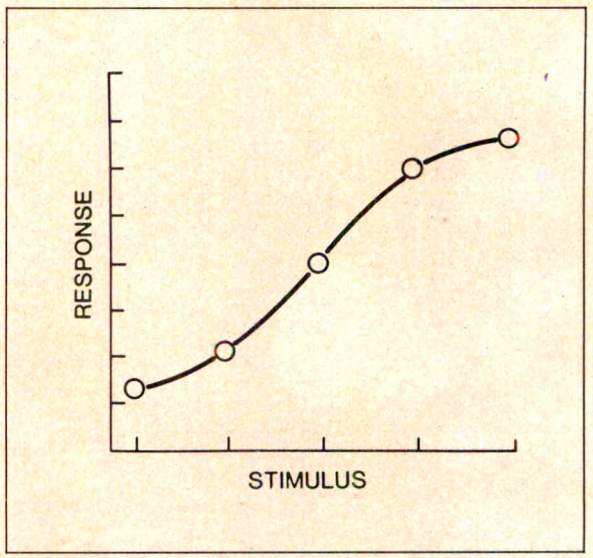

Fig 2.—Relationship between stimulus and response.

been devised to take into account the current state of the knowledge of immunological adverse reactions to foods, and confirmed manifestations have been divided as follows: reaginic reactions include anaphylaxis, abdominal pain, vomiting, diarrhea, angioedema, rash, urticaria, rhinitis, and asthma. Nonreaginic reactions include enteropathies such as vomiting, diarrhea, occult bleeding, protein-losing, and malabsorption; urticaria; allergic dermatitis; pneumonitis; and hemosiderosis.

Reaginic reactions are those that can be shown to have specific, identifiable IgE[11,12] or IgG reagin[13,14] associated with the clinical symptoms provoked by the particular food. These manifestations are almost exclusively limited to the GI tract, the skin, and the respiratory tract. Behavioral aberrations that have been noted in recent studies[15] have accompanied the discomfort created by the reaction occurring in another system. Older children who become irritable or have a mood change are able to report specific discomfort. Behavioral manifestations as the *sole* symptom of adverse reactions have not been objectively confirmed in studies at the National Jewish Hospital, Denver. Anaphylaxis to foods includes systemic manifestations; fortunately, it is quite uncommon in children.

Nonreaginic Reactions

Gluten-Sensitive Enteropathy.—Nonreaginic reactions to foods have been less clearly demonstrated, both clinically and immunologically, than reaginic reactions. Gluten-sensitive enteropathy (celiac disease) is the adverse reaction to food for which there is currently the most data supporting a nonreaginic immunologic mechanism as the etiology of the illness. Elegant in vitro[16] organ culture studies have shown that the villous architecture becomes flattened by the addition of gluten to the intestine-containing culture medium, but in addition to the gluten there is an endogenous effector that must be present or the histologic alteration will not occur. It is hypothesized that this effector is immunoglobulin. It has also been shown that the intestine of a gluten-sensitive patient produces increased amounts of specific antigluten antibody in response to challenge with gluten. This subject has been reviewed in detail elsewhere, and the interested person should read the details of these very informative investigations.[17-19]

In addition to the immunologic data, genetic investigations have shown a link between gluten-sensitive enteropathy and the histocompatibility antigen HLA-B8.[16,20] There is also a study showing an association between the disease and HLA-Dw3.[21]

Acute Gastroenteropathy.—Reactions consisting of vomiting and diarrhea with onset usually within 12 to 48 hours after ingestion of the offending food have been variously termed intolerance, allergy, idiosyncrasy, and intractable diarrhea. The two most common offending foods in this group are cow's milk and soybean derivatives. The best term for this type of reaction is acute gastroenteropathy.

Symptoms begin within a few weeks or months of the introduction of artificial formulas into the infant's diet. The problem is transient, so that between the ages of 2 and 3 years the child can tolerate the offending substance. If the responsible food is not identified and removed from the diet, the diarrhea may become intractable and sometimes fatal.[22,23]

The interval of hours to days between ingestion of the causative food and appearance of symptoms may be due to the time required for the pathologic process to become marked enough to produce symptoms. This is not properly referred to as a delayed reaction in an immunologic sense because the interaction of antigen and antibody or antigen and sensitized cells may occur within minutes of ingestion, though symptoms do not appear until the reaction has progressed to a point as yet undefined.

Examination of the mucosa of the jejunum in these children often reveals a characteristic flattening of the villi and infiltration of the lamina propria with lymphocytes, plasma cells, and eosinophils.[24-26] Because the lesion in the small bowel is a patchy lesion (unlike that in gluten-sensitive enteropathy), it may be missed when only a single biopsy is performed. Furthermore, the question of exactly when to perform the biopsy in relation to challenge with the offending food and production of symptoms is currently under investigation. An excellent, recent study has suggested that definitive information may be obtained by serial biopsies associated with challenge.[27] These children ordinarily do not exhibit evidence of reaginic sensitization nor do they have symptoms characteristic of reagin-mediated sensitivity.

Although soybean was mentioned above as a cause of acute gastroenteropathy, to my knowledge there is currently only one report in the literature of a biopsy showing the characteristic alteration of the mucosa after ingestion of soy.[28] In fact, the number of well-documented cases of adverse reaction to soy is, in my search of the literature, quite small considering the number of children ingesting soybean-derived formulas.[15,29-31] Thus, it would seem premature to become alarmed about the substitution of soybean products in place of cow's milk formulas in the vast majority of infants in whom this feeding is used.[32] This is especially true in view of the fact that infants produce circulating antibodies to proteins they consume without becoming symptomatic.[3-5]

Chronic Gastroenteropathy.—Within the last two decades there have been descriptions of infants and a few children suffering from several chronic symptoms: iron-unresponsive hypochromic anemia, edema, hypoproteinemia, and failure-to-thrive that is associated with occult blood and protein loss from the intestine.[33-35] It was found that removal of whole cow's milk from the diet allowed resolution of the symptoms, and subsequently these children were able to tolerate milk without apparent recurrence of their symptoms. Thus the condition, while chronic at an early age, seems to be transient with respect to future maturation as opposed to gluten-sensitive enteropathy, which is permanent.

A few of these patients[33] had episodes of urticaria, eczema, asthma, or rhinitis, suggesting involvement of a reaginic reaction. Unfortunately, the presence of reaginic antibodies was

not systematically sought; however, many of the patients were found to have elevated levels of circulatory precipitins to cow's milk proteins.[34,35]

Only a few of these patients have had small-bowel biopsies that revealed eosinophilic infiltration of the lamina propria, but the villi were normal or only slightly altered.[33]

More recently, Katz et al[36] have described a group of children with diarrhea, eosinophilia, and failure-to-thrive in whom biopsy of the gastric mucosa more regularly revealed infiltration with eosinophils than did biopsy specimens of the jejunum. This constellation of findings has been termed eosinophilic gastroenteritis. These children have not uniformly been found to have an identifiable offending food in the diet.

Chronic Pneumonitis.—In 1962, Heiner et al[37] described a group of infants in whom there was an association between high titers of precipitins to cow's milk proteins in the serum and a chronic pneumonitis. Subsequently, only a few other similar children have been described.[38-41] The infants' symptoms included vomiting, choking, coughing, and dysphagia, whereas diarrhea was unusual. Laboratory studies usually revealed hypochromic anemia and eosinophilia, and pulmonary infiltrates were found when chest roentgenograms were examined. In some cases, these infiltrates were found to be due to pulmonary hemosiderosis, and while hemoptysis was not usually manifested clinically in infants, examination of gastric contents showed the presence of macrophages containing iron. Removal of cow's milk from the diet resulted in resolution of the symptoms of these patients. The mechanism whereby these lesions were produced is currently unclear. It may be that a combination of nonreaginic and reaginic mechanisms are involved. Pediatricians should maintain an awareness of this constellation of symptoms so that other cases may be properly identified and the mechanism sought.

Current Knowledge of Immune Mechanisms in Nonreaginic Reactions.—It should be quite clear to the reader that the foregoing discussion constitutes a current attempt to classify certain syndromes by associated immunologic mechanisms. Ultimately, some of the immunologic reactions may be found to be etiologic. As we learn more about these conditions, this classification will become refined and more specific. The hiatuses in our knowledge serve as a challenge to continue to pursue the mechanisms of these illnesses.

Ultimately, the classification will probably be more complicated than presented here; however, there will eventually be more precise diagnostic tools to aid in the categorization of the individual patient. The pediatrician should concentrate on arranging an orderly diagnostic approach to each patient, based on current comprehension of etiologic mechanisms of adverse reactions to foods, both immunologic and nonimmunologic. (See next sections for practical procedures.)

DIAGNOSTIC PROCEDURES

Some people have adopted the attitude that if a food seems to be causing a reaction it should be removed from the diet and nothing further need to be done. This approach may be viewed as impressionistic empiricism and it leads to faulty diagnosis and nutritionally inadequate diets in some patients, especially young children. The proper approach expected of practitioners of scientific medicine requires more effort and thought. The practical solution is to ascertain the correct diagnosis by proper testing and then to prescribe the treatment based on this diagnosis. The next sections discuss an orderly approach to the problem, using currently available techniques; it is hoped that some of the myths surrounding the subject of diagnosis of food sensitivity will be dispelled.

Double-blind Food Challenge

The most important procedure in the study of adverse reactions to foods is the *objective, unbiased confirmation or refutation* of the history. This is accomplished by arranging that the food under suspicion be administered in such a fashion that neither the child nor the observers are aware of which food is being consumed. In children less than 5 or 6 years of age, blind challenge is performed by hiding the challenge food in some tolerated food. If the challenge food is a liquid, it can often be mixed with milk or formula that the child regularly consumes. Solid or semisolid foods can usually be hidden in applesauce. This procedure is often facilitated by use of a blender, which converts the mixture into a puree. The red applesauce created by blending strawberries in applesauce is well tolerated by young children who seem not to care about the color. In order that the mother and/or other observers remain unaware of the nature of the contents of the challenge, they may be asked to leave the room while the challenge is administered.

For children about 5 years or older, foods can be placed in capsules after having been crushed or dried. Many foods commonly incriminated as causes of adverse reactions are readily available in a dry, powdered form, eg, milk, egg white, and cereal grains (flour); peanuts can be easily crushed. Foods with a large liquid content need to be lyophilized before encapsulation, which does require the cooperation of someone with a freeze-drying apparatus. However, large quantities of foods may be infrequently prepared, and their shelf life seems to be in excess of a year, even at room temperature.

The procedure for double-blind challenge is as follows: eliminate the suspected food from the diet for at least one week; provide a diet of foods rarely causing reactions; introduce the challenge food in opaque capsules or hidden in nonoffending foods; arrange to have the subject and the observers blind; administer the challenge food in increasing amounts; and record manifestations systematically. Hospitalization may occasionally be required when the history strongly suggests a period of one or more days between the ingestion of the food and the onset of symptoms. If the child is taking medication for a chronic illness, it is essential that the medication regimen be stabilized and that the patient be as symptom-free as possible. Antihistamines should not be administered during challenges. The capsules are given in increasing doses,

with the initial dose, the size of the increments, and the length of time between doses being determined by the patient's history and by easily acquired experience. When a single dose of about 8 g has been tolerated blindly, the food is then given openly in usual portions prepared by customary means to be sure that the food will be tolerated. The latter procedure of giving the food openly ensures that considerations such as the effects of cooking or digestion are eliminated by the food being tolerated when eaten in usual portions prepared by customary means.

Placebo challenge is often not necessary, especially if more than one food is under suspicion so that the patient does not know what is in each challenge. When equivocal results are obtained, challenge with capsules containing dextrose as placebo is undertaken.

The importance of objective confirmation of even the most impressive history (except for anaphylaxis) cannot be stressed enough. A later section will show the results of food challenges. Children with histories of anaphylaxis to a food are *never* challenged with that food.

Skin Testing With Extracts of Foods

Textbooks on allergy almost invariably contain the statement that skin testing for foods is worthless or that these skin tests result in too many "false-positive or false-negative reactions." When the basis for these statements is sought in the scientific literature, it is not, to my knowledge, found. The idea that skin tests in which extracts of foods are used are not helpful is one of the major myths about allergy and is difficult to dispel. Just how these ideas have arisen is unclear, but it is the purpose of this section to refute these claims.

Extracts of foods (or inhalants) are like any other reagent used in a laboratory in that their efficacy cannot be automatically assumed. These extracts must be verified, which entails showing that they do not cause nonspecific or irritant reactions in anyone and that they do detect the presence of specific antibody. Using a group of eight food extracts to test 54 nonatopic individuals aged 2 to 60 years, it has been shown that these extracts do not produce nonspecific irritation. In addition, using extracts of 20 foods to perform a skin test on highly atopic children, it was shown that all children did not react to all extracts of foods, thus again refuting the idea of extracts of foods as irritants.[11]

Proof that extracts detect specific antibody ideally requires two pieces of evidence: correlation of the positive skin-test result with a positive double-blind food challenge; and another laboratory test to confirm the skin-test result. In studies performed at the National Jewish Hospital, both of these factors have been used in confirming the usefulness of skin testing.[11,12]

Having learned that extracts of foods used in skin testing are not nonspecific irritants and that they do detect specific antibody, it then becomes important to determine if they are helpful diagnostically. There are three major techniques whereby skin tests are applied to patients: (1) puncture test; (2) scratch test; and (3) intradermal tests. The puncture test is performed by applying drops of extract, usually of 1:20 or 1:10 weight/volume (W/V) concentration, to the back or arms. A small needle is then passed through the drop and into the skin far enough to create a small indentation but not far enough to draw blood. Scratch tests are performed by making a series of 5-mm scratches on the patient's back with a 26- or 27-gauge needle. Drops of extract of the same concentration as used for the puncture test are then placed over the scratches. Intradermal skin tests are performed by injecting intradermally the smallest amount of a 1:1,000 to 1:100 W/V concentration of extract that raises a visible bleb (usually about 0.02 cu cm). Controls performed simultaneously include a skin test with the diluent to determine nonspecific skin reactivity and a control with histamine to determine the reactivity of the patient's skin to that mediator. These controls are applied by the same technique as that used for the extracts.

Results are determined 15 to 20 minutes after application by measuring the size of the wheal and the erythema. There are many systems in current vogue for measuring skin tests. Measurement of the mean diameter of the wheal produced by the extract minus that of the diluent control yields the most helpful information. In the studies performed at the National Jewish Hospital cited in this review, a definitely positive skin-test response by the puncture technique is a wheal that is 3 mm or greater in diameter, after any bleb due to a reaction to the diluent control is subtracted (ie, a net wheal $\geq$3 mm).

The pediatrician should request of the allergist to whom he refers patients specific information regarding concentration of extracts, technique used, and interpretation of the results. The most important aspect of skin testing is proper interpretation of the results. As discussed in an earlier section, the presence of sensitization (as detected by a definite skin-test response) does not automatically predict the existence of clinical symptoms. There are a number of ways in which allergists determine whether or not skin-test responses are notable.

Determination of the clinical importance of skin-test results relies on three types of information: (1) the history may be so strongly correlated with the results of skin testing that there is no doubt about the association; (2) a challenge may be performed (blind food challenge, bronchial provocation test, or nasal provocation test as appropriate) to confirm the results of skin testing; and (3) extrapolation from the results of correlation studies may be used to predict the probability of a reaction occurring. For food sensitivity, the use of the double-blind food challenge is mandatory; selection of subjects for this procedure is discussed below.

Radioallergosorbent Test (RAST)

The RAST is a radioimmunoassay that has been used extensively by allergists to measure circulating levels of IgE antibody to specific antigens. Briefly, the test works as follows. An antigen is bound to a solid phase support (often paper disks), patient serum thought to contain IgE antibody specific for the antigen is added,

then a radiolabeled anti-IgE is added and after proper incubation and washing at each step the mixture can be counted in a gamma-radiation detector and the quantity of antigen-specific IgE can be determined.

There has been some controversy about the use of this test amongst allergists, especially for use in food sensitivity. It has been said to be superior to skin testing because it is "less dangerous" and "more reliable." As discussed above, skin testing, properly performed and interpreted, is reliable and clearly not dangerous. Recent literature has shown,[42] and many workers in the field agree, that the RAST is no more sensitive or reliable than skin testing, although that conclusion is not always clearly stated in journal articles. Problems with the RAST are that it detects circulating IgE, not cell-bound IgE, the latter being the portion responsible for mediator release; it is expensive; it requires use of radiation and attendant precautions; the results are not immediately available; circulating IgG antibody may interfere with the test; and the RAST, like the skin test, is only semiquantitative as performed in the majority of commercial laboratories. The test is very useful for research purposes and for standardization of allergenic extracts. At present, it is our opinion that the general use of the RAST for allergy testing is not appropriate; the test should be limited to research applications by persons who understand the limitations of the information provided.

Determination of Circulating Nonreaginic Antibodies to Food Protein

Investigators in the past have examined circulating levels of antibodies to cow's milk proteins.[3,43] These studies have measured the quantity of circulating antibody but have usually analyzed the data collected in terms of prevalence or incidence of detectable antibody rather than in terms of quantity. It has become well known that children with a normal immune system who drink cow's milk will make antibodies to some of the proteins[4,5,44,45] (and aforementioned communication of May et al).

More recently, children with various symptoms have been examined to see if the quantity of antibody to food proteins in the circulating blood provides any useful information. Differences have been found between levels of antibodies to milk protein in young children (<3 years of age) who have adverse reactions to cow's milk (both reaginic and nonreaginic) but who have consumed enough milk so that substantial quantities of antibody have been produced. In addition, older children have been found to have elevated levels of circulating antibodies to cow's milk protein (considerably above age-matched controls) when they have symptomatic food sensitivity to another food (eg, peanuts) but can drink milk with apparent impunity.[4,5]

This test is not widely available at present; however, further research, especially in children less than 3 years of age, may show it to be a test that would provide diagnostic assistance. Space does not allow a full explanation of the technique. It is a type of radioimmunoassay that could easily be performed in the diagnostic laboratory of a reasonably sized hospital.

GI Biopsy

Examination of biopsy specimens of the jejunum has long been the definitive method for making a diagnosis of gluten-sensitive enteropathy (celiac disease). It remains the only way at present to clearly confirm the diagnosis when accompanied by withdrawal and challenge with gluten. Biopsy studies are also the only current means by which to study the mechanism of gluten-sensitive enteropathy.

As mentioned earlier the histopathology of cow's milk protein-sensitive enteropathy, and the reported case of soy protein-sensitive enteropathy proven by biopsy results, are substantially the same as that seen in gluten-sensitive enteropathy. Gluten-sensitive enteropathy is a diffuse process involving the entire small bowel down to whatever level it has progressed. Cow's milk protein-sensitive enteropathy by contrast is a patchy lesion, and thus the altered mucosa may be missed by a single biopsy. Furthermore, the biopsy does not provide information about the degree of involvement. Despite these limitations, study of biopsy specimens of the small bowel will remain a very useful and important technique until better diagnostic tests are developed.

Katz et al[36] have shown that biopsy of the gastric mucosa may be useful in determining eosinophilic gastroenteritis when the small-bowel biopsy results are normal. The stomach is obviously easier to perform biopsy on than is the small bowel, and when eosinophilic gastroenteritis is suspected, a gastric mucosal biopsy is appropriate.

In children with a colitis syndrome secondary to cow's milk protein, results of rectal biopsies have been shown by Gryboski[46] to be useful. At present there is, to my knowledge, no good evidence that rectal biopsy is helpful diagnostically when the injury is in the small intestine. However, since rectal biopsy is much easier to perform, further investigation in this area seems warranted.

Other Diagnostic Procedures

Three other areas of immunology have been investigated in a preliminary manner with regard to their possible relationship to food sensitivity: alterations of complement, immune-complex formation, and cell-mediated immunity.

Changes in complement levels have been measured during cow's milk challenge, but the data conflict with one study that shows a change and another that does not confirm this result.[24,47] Another study reported preliminary evidence of an alteration in the alternative complement pathway while subjects were drinking cow's milk.[48] One baby had complement levels that were altered during a symptomatic sensitivity reaction to rice, which was also associated with the presence of reagin.[49]

The presence of circulating combinations of food antigen and antibody to food (immune complexes) has just begun to be looked for in patients with suspected food sensitivity. Some claims have been made about the possible association between immune complexes from milk protein and nephrotic syndrome, but these have

not been, to my knowledge, rigorously confirmed by use of the scientific method.[50] In an effort to explain the mechanism of these reactions, recent studies have begun to look for antibody and antigen in the tissue of patients who react to gluten[17,18] and to milk.[51]

To my knowledge, at present the association of cellular immune processes and food-sensitivity reactions has been inadequately examined, and the data for patients with gluten-sensitive enteropathy is inconclusive.[52] May and Alberto[53] have shown that lymphocytes from normal children and children with food sensitivity can be stimulated to the same degree by food proteins.

It seems clear that these three areas are in need of systematic, scientific investigation in order to determine if they play a role in immunological reactions to foods.

A PRACTICAL APPROACH TO PATIENTS COMPLAINING OF ADVERSE REACTIONS TO FOODS

History and Differential Diagnosis

As in most areas of pediatric practice, the most important part of an evaluation for a patient complaining of an adverse reaction to a food is the history. The following facts should be obtained for every child: (1) a free-flowing description of the symptoms and course of the reaction; (2) time between ingestion of the food and onset of symptoms; (3) when the reaction last occurred; (4) how many times the food has caused a reaction; (5) what quantity of food is required to evoke the reported reaction; and (6) what is the character of any stools, nasal discharge, sputum, etc.

When the history has been obtained, the physician is usually faced with a list of manifestations as discussed earlier. It is then necessary to consider the differential diagnosis and determine which category is most likely to explain the described symptoms.

Children 3 Years of Age or Older

Present knowledge allows division by age of the diagnostic approach for children into two groups when a food sensitivity reaction is suspected. In children 3 years of age or older, skin tests with extracts of foods are performed as previously described. When the puncture skin test with a 1:20 W/V concentration of extract gives a definitely positive result, the child undergoes a double-blind food challenge. If the puncture test is negative, the food is placed openly in the diet and the child is observed for a reaction.

The cases of 132 children 3 years of age or older with an impressive history of an adverse reaction to a food were evaluated in this manner. The adverse reaction was confirmed in only 42% of the children (22% of the double-blind food challenges). There were 26 reactions to peanuts (a legume); 15 to other nuts; 11 to egg; six to milk; two each to soy and shrimp; and one each to banana, tuna, chicken, and trout. In these older children, the puncture test was definitely positive for each food for which the double-blind challenge was confirmed, and all reactions occurred within two hours of the challenge. Reactions were caused by 20 to 8,000 mg of dried food. Gastrointestinal manifestations were evoked most commonly, skin reactions were next, and respiratory reactions were least common. Alterations in behavior accompanied some of the above reactions but did *not* occur as *sole* manifestations and were all related to discomfort experienced from the primary reaction. No child had anaphylaxis or a reaction requiring any more than minor treatment with diphenhydramine hydrochloride.

In the 58% of children whose history of food sensitivity was not confirmed, the food was tolerated when reintroduced into the diet in usual portions prepared by customary means. It is not possible to easily explain how these children each came to have an impressive history of adverse reaction except to say that many symptoms were spuriously associated with ingestion of various foods. It will be noted that none of the confirmed reactions were to chocolate, strawberry, or tomato. There are probably children who do react to these foods, but the number of these reactions is certainly much less than is commonly believed.

It should be emphasized that in this age group, in this study, all children who had an objectively confirmed symptomatic sensitivity to a food were identified by the puncture skin test using a 1:20 W/V concentration of verified extracts. Verification of these extracts, as previously described, has been found to be of utmost importance.

Children Less Than 3 Years of Age

In children less than 3 years of age, it is of primary importance to objectively confirm the existence of the adverse reaction. Research is continuing in an effort to determine which diagnostic tests might be helpful in this age group. Skin testing is quite useful even in young children if it is properly performed and interpreted. The cases of 71 children who were less than 3 years of age and who had impressive histories of adverse reactions to foods were evaluated. Symptoms were evoked in 26 (37%) of the children and in 38 of 120 (32%) double-blind food challenges. Of the 38 reactions, 13 were to milk; seven were to soy; four were to peanut; and one each was to fish, wheat, and squash.

The 26 children who reacted may be divided into two groups. Twenty subjects experienced symptoms within two hours of the food challenge, and in these the puncture skin test, performed as described, were positive for 26 of 30 positive food challenges. This illustrates that the puncture test is useful even in these young children. These children would be classified as having had reagin-mediated symptomatic sensitivity.

Six children had the onset of symptoms more than four hours after the double-blind food challenge. The puncture test was definitely positive for only one of the eight reactions to food and this result may not have been related to the mechanism that caused the reaction. The manifestations in these children all involved the GI tract or the skin. They would be classified as having had nonreagin-mediated symptomatic sensitivity.

When the child's problem is chronic diarrhea that is thought to be precipitated by food ingestion, an attempt

should be made to associate the onset and perpetuation with one or more foods so that a specific diagnosis can be formulated. Whenever appropriate, a small-bowel biopsy should be performed.

At present, circulating antibodies to foods are being determined in serum from these children at the National Jewish Hospital because the results aid in determining which cases to evaluate most vigorously. Perhaps this test will be more widely available in the future.

Recapitulation of Practical Approach

The following is a brief statement of the current practical steps used at the National Jewish Hospital for evaluation of the cases of children with a history of adverse reaction to a food. First, the history and physical examination are completed, the differential diagnosis is considered, and appropriate laboratory tests are undertaken to eliminate nonimmunologic mechanisms. If the child is over 3 years of age and has an impressive history of reaction, a puncture skin test is performed. If the puncture skin test is positive, a double-blind food challenge is then performed. If the double-blind food challenge is positive, the food is then eliminated from the diet. If the double-blind food challenge is negative, the food is then reintroduced openly into the diet and the child is observed to be sure that no reaction is occurring.

If the puncture skin test is negative, then the food is reintroduced openly into the diet and double-blind challenge is not performed unless there is some untoward reaction that is observed when the food is eaten openly. It should be emphasized that it is not always necessary to use a placebo for the elimination of bias; if this is required, dextrose can be used in capsules.

In children less than 3 years of age the approach is somewhat different. If the history is impressive, a double-blind food challenge will be performed regardless of the results of the puncture skin test. In these situations skin testing is generally used to attempt to determine the mechanism responsible for any reaction that is produced. Mucosal biopsy is undertaken in those children having diarrhea in whom the etiology and/or pathogenesis cannot be determined.

TREATMENT

Avoidance

At present, the optimal method of treating symptomatic sensitivity to food is elimination of the offending food category from the diet. Very few children are sensitive to a multitude of foods in the diet, and when this occurs they can be fed an elemental diet (Nutramigen, Pregestimil, Vivonex) until their symptomatic sensitivity subsides. Children may be sustained for prolonged periods (months) on severely limited but nutritionally wholesome diets. For most children, the elimination of a single food is usually inconvenient but does not create an insurmountable problem for the family.

Drugs

Antihistamines, cromolyn sodium, and corticosteroids have been used to treat food sensitivity. It is my opinion that insufficient evidence is available to support the use of any of these drugs except for corticosteroids in intractable diarrhea of infancy.[22] Cromolyn has been shown to have some efficacy in certain situations[54]; however, it appears to have been unnecessary in any of the children treated at the National Jewish Hospital. In addition, there should be concern that while the clinical symptoms may be ameliorated, an immunologic and/or biochemical reaction may be occurring with potential long-term hazards.

Antihistamines have not been shown to be efficacious for use in subjects with food sensitivity and should not be used for this purpose until controlled studies have proven their utility.

Immunologic Manipulations

Current knowledge in immunology would allow the hypothesis that if specific antibody in the intestine (presumably of the IgA isotype) could be stimulated, then subjects with symptomatic sensitivity to foods might be protected by this antibody. Studies testing this idea have been performed in animals[6] but are far from being carried out in humans. Administering foods or extracts in small amounts orally or by injection are methods currently in vogue by some practitioners but have yet to be shown by scientific methods to have any validity. Attempts at "oral desensitization" or alteration of the immune response should currently be regarded as experimental. On the other hand, it may be appreciated that the stimulus-response relationship, as discussed earlier, supports the observation that a child may be able to ingest small amounts of an offending food whereas larger quantities evoke symptoms.

IMMUNOLOGY OF INFANT FEEDING

The immunology of breast milk and infant feeding has been reviewed in detail recently,[55,56] but a few comments seem warranted in a review of food sensitivity. A number of questions have been raised with regard to the immunologic response of the neonate and the content of the diet. Three will be considered here.

Does prolonged breast-feeding decrease the incidence of allergy, especially in children with a family history of atopy? This has been a controversial area for a number of years, with studies supporting both positive and negative answers. A recent study by Saarinen et al[57] in Finland presents evidence that prolonged breast-feeding (≥six months) decreased the incidence of symptoms of allergy in children who had a family history of allergy. All studies like this one have the problems of the continuance of long-term evaluation of subjects and of the influence that the loss of some subjects may have on the analysis of the data. Nevertheless, this is an area worthy of research pursuit because of its practical pertinence to every parent and every pediatrician.

What immunologic components does breast milk contain that may augment or influence the immunity of the infant? Breast milk has been shown by numerous investigators to contain antibodies to various substances, especially bacteria and viruses, macrophages, lymphocytes,

neutrophils, complement, and enzymes.[55,56] Most important from a sensitivity point of view is that breast milk can transmit antigenic material that would cause infants to have a clinically notable reaction. Studies at the National Jewish Hospital have identified children who have had GI, skin, and respiratory symptoms after their mothers have ingested foods.[15] Whether the protein is absorbed by the mother and transmitted intact to the infant or whether antigenic fragments are passed remains to be determined.

A study by Harris et al[58] has shown increased numbers of IgE-containing plasma cells in intestinal biopsy specimens of babies in whom colic was associated with milk ingestion. This controversial area requires further investigation and confirmation. At present, it seems premature to administer an elimination diet to every colicky infant; however, the physician should inquire about the possible onset of symptoms in relationship to feeding.

Does the level of IgE in umbilical cord sera predict the development of atopic symptoms? Studies by Dannaeus et al,[59] Orgel et al,[60] and Kjellman and Johansson[61] present data supporting the suggestion that elevated umbilical cord or serum IgE will be found more often in children in whom atopic symptoms eventually develop. The mechanisms whereby these findings occur require systematic investigation. Studies need to be designed to determine whether breast-feeding and/or low-antigen diets in the early months of life can be used in these children to reduce the later development of sensitivity reactions.

These and other questions, including determination of the incidence of sensitivity reactions to foods, are being investigated in numerous centers. The answers from this research should eventually help pediatricians and parents to better manage their children's diets.

COMMENT ON UNPROVEN SYNDROMES

There is currently a great deal more being written in the popular press for lay consumption on food allergy than is to be found in the medical literature. Clearly, many of the symptoms attributed to food allergy have nothing to do with the immune system. One of the most popular ideas is that "hyperactivity" is produced by food additives including some natural constituents and that it is produced by intake of sugar. All pediatricians should read carefully the studies by Harley et al,[62,63] which constitute the best attempts to date to study the Feingold hypothesis by using the scientific method. The issue of sugar and behavior has not been, to my knowledge studied scientifically; however, the patients seen at the National Jewish Hospital with this complaint all have very strong beliefs about how they will respond. In the few patients evaluated by use of double-blind challenge, the history has not been confirmed either during blind challenge or when the sugar is reintroduced into the diet in the incriminated form.

Certainly, pediatricians are plagued by these problems. Physician and layman alike should be encouraged to become more critical of sources that make sweeping claims without substantial support. It is definitely easier to blame a child's behavioral problems on the diet than it is to evaluate family interactions. This is true for both physicians and parents. One other problem in this field is the difficulty in achieving a universally accepted definition of hyperactivity.

The recent attention given to hyperactivity has tended to eclipse the other common but unsubstantiated diagnosis, namely, the tension-fatigue syndrome. Unfortunately, both of these groups of children have had their diet blamed for their problems, this being based on uncontrolled observations, anecdotal testimony, and empirically applied diets. It seems appropriate to repeat a statement first written elsewhere: "a drop of truth may rarely be tossed up from the depths of the sea of folly, but a dependable means is needed to pick out a drop of sense in a spray of nonsense. For this purpose the success of the scientific method places it well above empiricism."[64] The difficulty of applying the scientific method in certain situations does not absolve us from attempting its application to the best of our ability. Pressure from vocal groups with fervently held beliefs should not be the basis on which opinions and treatments are based by either the medical profession or regulating agencies. At present, most of these problems should be regarded as medical problems, not public health matters.

Finally, there are a number of unproven laboratory tests that are being regularly applied to patients with suspected adverse reactions to foods. These have been reviewed elsewhere and will not be repeated here.[65] Pediatricians should ask critical questions about interpretations of these tests when their patients are evaluated and treated by use of these methods.

CONCLUSIONS

In this review of food sensitivity, an attempt has been made to dispel some of the myth surrounding this subject. The important points to be remembered are that (1) an organized approach is available and has been listed if one takes the trouble to see that it is applied; (2) histories, even the most impressive ones, must be confirmed or refuted in an *unbiased, objective* manner before a diagnosis is made and a mechanism is sought; (3) there are currently useful laboratory techniques to aid in diagnosis of food sensitivity; and finally, (4) further research in this area is crucial for improving diagnostic tools, defining the mechanisms, and discovering an effective treatment or a method of prophylaxis.

Charles D. May, MD, provided guidance in the studies described herein. Linda Remigio provided technical assistance and, with Dr May and Georgia Wheeler, helped in the preparation of the manuscript.

Special Feature

Radiological Case of the Month

Lionel W. Young, MD; Contributed by Marvin S. Kogutt, MD

An 830-g boy was born to a 17-year-old, primigravida mother after 27 weeks' gestation. At the time of delivery, he had no spontaneous respirations and was admitted to the Newborn Intensive Care Unit, Ochsner Clinic, New Orleans. He was intubated, and ventilation therapy was begun by bag; Apgar scores were 4 and 6 at one and five minutes. Severe respiratory distress was present with grunting, intercostal retractions, and decreased breath sounds bilaterally. The chest roentgenograms (Fig 1) were obtained at that time.

The infant was placed under a radiant warmer, and positive pressure ventilation therapy was begun with a respiratory rate of 16 per minute, a pressure of 20 cm H_2O, and a forced inspiratory oxygen of 75%. His condition remained relatively stable over the first 48 hours. However, respiratory distress continued to worsen, and he required increased respirator support. At 3 days of age, he became severely acidotic, but his condition subsequently stabilized and he required continuous high-pressure ventilation therapy. A chest roentgenogram (Fig 2) was obtained.

Over the next two days, the infant continued to require respirator support, and respiratory distress progressed. On the fifth day of life, he underwent sudden cardiovascular collapse with decreased breath sounds, and a friction rub was noted over the heart. Bradycardia and hypotension persisted in spite of attempts at resuscitation. A roentgenogram (Fig 3) was obtained immediately prior to the infant's death.

Denouement and Discussion

Systemic Air Embolism Secondary to Respiratory Therapy

Fig 1.—Initial posteroanterior (top) and lateral (bottom) chest roentgenograms demonstrate bilateral reticulogranular pattern with peripheral air bronchograms and scattered punctate lucencies compatible with hyaline membrane disease/respiratory distress syndrome. Note endotracheal tube.

Fig 2.—Chest roentgenogram obtained at 3 days of age demonstrates linear, nonbranching lucencies extending into peripheral lung fields (arrows), indicative of pulmonary interstitial emphysema.

Fig 3.—Chest roentgenogram obtained at 5 days of age; preterminal. Air is present within cardiovascular system, including heart (broken arrows), hepatic veins (curved arrows), and inferior vena cava (open arrow).

Positive pressure ventilation is commonly used in the treatment of neonatal respiratory distress syndrome and is associated with an increased survival rate from the condition. Complications of positive pressure ventilation, specifically extra-alveolar and extrapulmonary air leaks, have become more frequent. Air-leak phenomena may result in a spectrum of abnormalities ranging in nature from clinically mild to severe and fatal.

The initial event is alveolar rupture. Air may then escape from the alveoli through the interstitial perivascular spaces and lung parenchyma to enter one or more potential spaces.[1-3] These may include the mediastinum, the pleura, the pericardium, the peritoneum, and the cardiovascular system. These spaces have the potential for communication, and any combination of these events may occur.[4,5]

The occurrence of systemic intravascular air embolism secondary to positive pressure ventilation usually, but not invariably, occurs as a late event in conjunction with other complications. Though the exact mechanism is unproven, the entrance of air into the vascular system most likely results from either the formation of alveolar-capillary or bronchovenous fistulae following alveolar rupture.[6-8] This may occur when the intra-alveolar exceeds the left atrial pressure, causing reversal of the normal pressure gradient with escape of air from the alveoli into the pulmonary veins.[7] Air may then travel directly to the heart and then into the systemic circulation.

The radiologic diagnosis is made by visualization of air within the systemic vascular circulation. Air is consistently and simultaneously present in both the arterial and venous circulations.[9,10] It is postulated that air enters the venous circulation through the capillary bed.[7] This venous air is consistently present in the hepatic veins. Intracardiac air is also a consistent finding and should be differentiated from pneumopericardium or pneumomediastinum. Postmortem roentgenograms to verify the presence of air should be interpreted with caution since rapid postmortem accumulation of gas is a frequent occurrence and may result in incorrect interpretation.[11]

The diagnosis of systemic air embolism is usually determined roentgenographically after severe clinical deterioration. With the widespread use of positive pressure ventilation, it is likely that systemic air embolism will become more frequent.

Denouement and Discussion

Enteric Duplication Cyst

Fig 1.—Left and right, respectively, Enteric duplication cyst of tongue (at birth and age 8 weeks).

Fig. 2.—Transillumination of cyst.

Manifestations

Enteric duplications can occur anywhere along the alimentary tract. Most often found in the ileum, duplications have been reported to occur from the tongue to the anus. The duplication may be either tubular or cystic and is usually lined with mucosa similar to that of the adjacent alimentary tract structures; however, the mucosa may be similar to the more distant alimentary structures.

Enteric duplications occurring in the tongue are unusual, with, to our knowledge, less than ten cases reported. Manifestations, which are usually related to feeding difficulties, depend on the size of the lesion, the presence of communication with the oral cavity, compression of adjacent structures, and the presence of heterotopic mucosa. Respiratory embarrassment due to an enteric duplication cyst occurring in the tongue has not (to our knowledge) been reported. Although enteric duplications, in general, have a high incidence of associated anomalies (vertebral and gastrointestinal), no other anomalies have been reported in the published cases of duplications occurring in the tongue.

The differential diagnosis includes cystic hygroma, hemangioma, lymphangioma, ectopic thyroid, macroglossia, and rhabdomyoma. A thyroid scan should be performed to be certain that the infant's only thyroid tissue is not surgically removed.

Genetics

Enteric duplications do not appear to be inherited. There are several theories concerning their etiology, but none can explain the origin of all duplications. Of the theories proposed, persistence of fetal enteric diverticula would seem the most plausible for duplications occurring in the tongue.

Treatment

Careful surgical excision is the treatment of choice. If present at birth and not interfering with feeding or breathing, surgery can be postponed until symptoms occur. Concern over possible respiratory embarrassment is obvious; however, feeding difficulties usually precede any respiratory compromise.

Live-Born Triploid

Approximately 60% of all human spontaneous abortions during the first trimester of pregnancy are associated with chromosomal aberrations of the conceptus. Nearly 20% of these karyotypes are triploid,[1,2] ie, 66 autosomes and three sex chromosomes. Hence, triploidy is one of the most frequent chromosome aberrations in human abortuses.

Developmental arrest followed by spontaneous abortion of the triploid conceptus most often occurs between three and six weeks after fertilization[3]; however, there are reports (summarized in references 4 and 5) of 31 cases of full triploidy that survived past 24 weeks of gestation. In a recent study of nearly 60,000 consecutive live-born infants, only one was a triploid.[6] Though survival was usually limited to a few days[7] in the 11 reported cases of pure triploidy, Fryns et al[8] described a female infant who lived for two months after birth.

Triploid infants are reported to share a wide range of malformations; however, there is marked variability in the presence and/or expression of these anomalies. Even though no constellation of findings is pathognomonic,[9] the disorder can be suspected from clinical findings. This report describes a triploid male infant who lived for 14 hours after birth.

Report of a Case.—A 1,110-g male infant of 33 weeks' gestation was born to a 29-year-old, gravida 2, para 1 woman at St Luke's Hospital, Denver. The pregnancy was complicated by recurrent vaginal bleeding during the first trimester, poor fetal growth, and premature rupture of membranes at an estimated 32 weeks' gestation. Serial ultrasound examinations in the second and third trimesters corroborated the diagnosis of intrauterine growth retardation but failed to reveal any anomalies. The mother enjoyed good general health during the pregnancy and had not taken birth control pills in the preceding 12 months. She did not take alcohol, drugs, or medications, nor did she smoke. The father was 29 years old. Their first child was alive and well.

Attempts were made to inhibit labor by use of intravenous alcohol to allow transfer to Denver from her home in Nebraska, 200 miles away. Labor progressed, however, leading, 48 hours after membrane rupture, to delivery by cesarean section because of meconium-stained amniotic fluid and fetal bradycardia. The amniotic fluid volume was markedly reduced. The infant was depressed at birth and required a short period of positive pressure ventilation therapy with oxygen. Regular respirations were established in five minutes. Apgar scores were 2 and 6 at one and five minutes, respectively.

Clinical examination revealed the following: a growth-retarded, premature, male infant with craniofacial dysmorphism and other anomalies. Birth length was 37 cm (< tenth percentile), and birth weight 1,110 g (< tenth percentile). The cranial vault was large in relation to the face and body, and the occipitofrontal circumference measured 30.5 cm (45th percentile). The metopic suture was open to the glabella; other sutures were normal, but there was a large third fontanel. The scalp hair pattern was normal, and transillumination was within normal limits. There was an antimongoloid slant to the eyes, and, apart from the impression of a small nose, mouth, mandible, and tongue, these structures, the ears, and the remainder of the face and neck were normal.

The chest was small (circumference, 20.5 cm), with a marked thoracic scoliosis. The testes were not palpable, and a mild degree of glandular epispadias was present. The anus was patent, but the sphincter was lacking in tone. A right positional calcaneovalgus deformity was present. There was syndactyly of the third and fourth digits of all four limbs.

The infant demonstrated early respiratory distress, this being treated with oxygen. Spontaneous limb movements were present, but primitive reflexes (Moro's, grasp, root, and suck) were absent. A chest roentgenogram showed small hemithoraces consistent with pulmonary hypoplasia but no parenchymal disease. The scoliosis was evident. The cardiothymic silhouette was normal. The infant died in the next 14 hours of progressive respiratory failure.

Chromosome studies were done on peripheral blood lymphocytes obtained before death. Twenty cells were counted and all revealed a complete triploid karyotype, 69,XXY. No diploid cells were observed.

At autopsy, the brain weighed 300 g and had a normal gyral pattern for gestational age and no structural abnormalities. The thoracic cavity was small and cone-shaped. The left lung was bilobate and weighed 3.5 g; the unilobate right lung weighed 2 g. Microscopic examination revealed atelectasis, congestion, and amniotic squamocellular debris. The heart weighed 10 g and was normal.

Abdominal organs were in normal position and grossly unremarkable. Each kidney weighed 3.6 g; histologic findings were normal. Each adrenal gland weighed 0.4 g and consisted of about 90% fetal cortex. Two small testes were found in the pelvis.

The placenta weighed 170 g (fetoplacental ratio, 6.5) and was otherwise normal both grossly and microscopically. The umbilical cord was thin, with a single artery.

Comment.—The live birth of a nonmosaic triploid infant is a rare event. This is not surprising since there are arguments to suggest that a fetus will not survive if more than 5% of the haploid genome is triplicated.[10] Though there is no pathognomonic constellation of anomalies, live-born triploid infants show a number of common clinical stigmata and congenital malformations.[5,9,11,12]

The present case illustrates many of these, eg, first trimester bleeding; craniofacial anomalies including large posterior fontanel, low-set ears, and open metopic suture; syndactyly on all four limbs; adrenal hypoplasia; small penis; cryptorchidism; and intrauterine growth retardation. Our patient did not have cardiac, renal, or biliary tract anomalies. There was no omphalocele, abdominal organ abnormalities, spina bifida, or meningomyelocele.

In contrast to most other published cases, our patient had severe pulmonary hypoplasia, and the placenta was histologically normal. Oligohydramnios was diagnosed by ultrasonography ten weeks prior to delivery, and the small thorax observed at birth suggests that the hypoplastic lungs could have been the consequence of external compression of the thoracic cage resulting from the oligohydramnios. Since the pulmonary defect appears to be a deficiency of late fetal development,[13] it is unlikely that pulmonary hypoplasia would be reported in early triploid abortuses. Placental enlargement and/or hydatid

degeneration of the chorionic villi are often reported in triploidy; however, the placenta may be morphologically normal in term triploids.[9]

Theoretical mechanisms of origin of full triploidy have been extensively reviewed by Niebuhr[11] and include mitotic abnormalities in the germ cell precursors, errors in the first or second meiotic division of oocytes or spermatocytes, and dispermy. The origin of triploidy has been demonstrated in several cases by using various chromosome markers,[14] and it appears that two sets of paternal chromosomes are most frequently involved.[15]

There is no discernible effect of parental age. However, future pregnancies may be at increased risk for either polyploidy or aneuploidy. Boué and Boué[16] established the karyotypes of two consecutive spontaneous abortions in 43 women. One woman had two consecutive triploid abortuses, and eight others had triploid abortus each. Of these eight women, five had other abortuses with chromosomal anomalies, mostly autosomal trisomies. It would be interesting to know the frequency of chromosomal aberrations, especially complete and mosaic aneuploidy and polyploidy, in infants with nonrenal oligohydramnios.

Milk Curd Obstruction Mimicking Necrotizing Enterocolitis

Intestinal obstruction in the newborn due to milk curds was first observed by Cook and Rickham[1] in 1969. The diagnosis has been confused with necrotizing enterocolitis (NEC).[2] A recent experience with an infant with milk curd obstruction who had clinical and roentgenographic evidence of NEC prompted this report.

Report of a Case.—An 880-g boy of 28 weeks' gestation was delivered vaginally after prolonged rupture of fetal membranes for more than 120 hours and administration of a course of betamethasone (12 mg/day for two doses) five days prior to delivery. Apgar scores of 8 and 4 at one and five minutes, respectively, led to bag and mask ventilation with 100% inspired oxygen. Initial problems included hyaline membrane disease that required prolonged mechanical ventilation, jaundice that required a double volume exchange transfusion, and seizures. Continuous feedings through a tube placed in the second portion of the duodenum consisting of commercially available formula (Similac LBW 24) were progressively increased until total enteral nutrition was achieved by the 13th day.

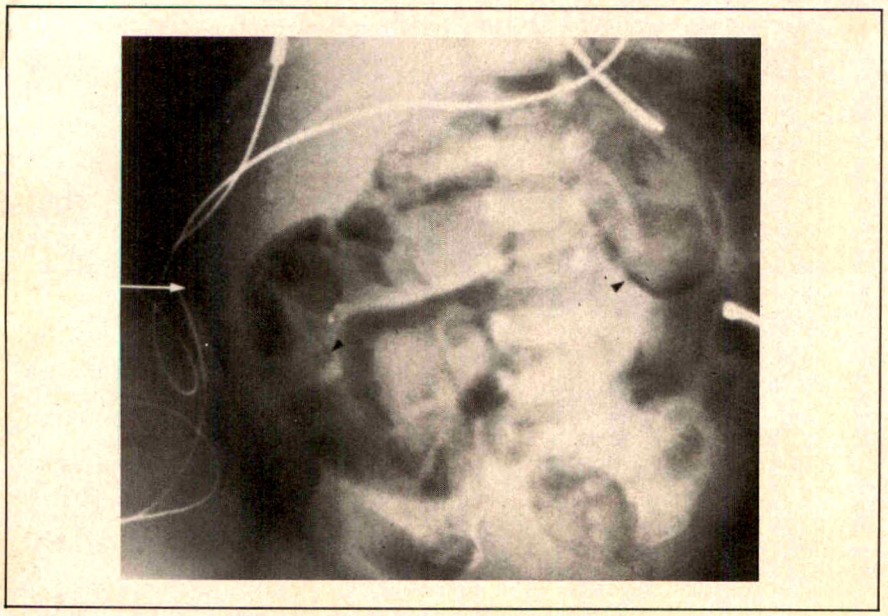
Apnea ultimately led to reinstitution of mechanical ventilation 19 days after birth. On the following day, dehydration was noted despite a fluid intake of 180 mL/kg/day. On day 22, abdominal distention and evidence of poor tissue perfusion accompanied roentgenographic evidence of pneumatosis. The initial roentgenogram was interpreted as showing possible free air (Figure).

A diagnosis of necrotizing enterocolitis with possible intestinal perforation was made. At surgery, the bowel appeared normal except for milk curds that obstructed the distal 30 cm of ileum. No perforation was found. An enterostomy was performed and the curds were removed. After a prolonged course complicated by recurrent apnea, the infant was discharged 99 days after birth with a weight of 1,780 g. No intestinal problems were noted in follow-up evaluation one month later.

Comment.—Milk curd intestinal obstruction has been reported in both term[3] and preterm[2,3,5] infants. Although considered unusual, it was reported by Dickson et al[6] to account for 17 of 238 neonatal intestinal obstructions over an eight-year period. Findings of abdominal distention and obstruction and dense intraluminal masses surrounded by a halo of air[4] have been described as characteristic clinical and roentgenographic features. Peritoneal air secondary to perforation has also been found.[1,4] Although infants as old as 6 weeks[7] and infants breast-fed during the first week[1] have been reported with the condition, the disorder is most common five to 14 days after birth in formula-fed infants.

The cause of this condition in the neonate is unclear. Cook and Rickham[1] suggested a relation to early provision of concentrated formula feeding accompanied by defective protein and amino acid absorption. Several recent reports describe lactobezoars in premature infants, all but one of whom were fed a special 800 calorie/L formula.[8,9] Schreiner et al[10] discussed several other potentially associated factors in these infants, and suggested that the condition is probably caused by multiple factors.

In the present case, a premature infant was fed an 800-calorie/L formula specifically designed to be given to low-birth-weight infants by continuous intraduodenal infusion. Abdominal distention and circulatory collapse, and roentgenograms that showed pneumatosis intestinalis, suggested the diagnosis of NEC. However, a milk curd obstruction was found at the



Anterior-posterior portable abdominal roentgenogram. Arrowheads indicate linear streaks in bowel wall interpreted as pneumatosis intestinalis. Large arrow indicates air in dilated bowel loop surrounding impacted milk curd.

time of laparotomy. Widespread use of concentrated formulas and transpyloric feedings may contribute to an increased incidence of obstruction of the intestine by milk curds. Since this condition may appear as NEC both roentgenographically and clinically with poor perfusion, efforts must be made to exclude this diagnosis. In retrospect, the onset of these signs in an infant who was tolerating intraduodenal feedings of this special low-birth-weight formula might well have alerted us to the correct cause. The reported roentgenographic finding of intraluminal air surrounding a milk curd, incorrectly interpreted as possible free air in this case, may be helpful in distinguishing milk curd obstruction from NEC.

Promethazine-Induced Acute Dystonic Reactions

Dystonic crises are usually associated with the antipsychotic phenothiazines. They are considered to be idiosyncratic reactions to phenothiazines as well as to other centrally acting agents such as the tricyclic antidepressants.[1] The phenothiazine group of drugs represents a variety of agents that differ in their pharmacologic effects. Promethazine hydrochloride is usually employed for its H_1 antihistaminic properties, and less frequently for its sedative-hypnotic effect. Some of its actions on the CNS have been ascribed to its potent anticholinergic activity.[2,3] Textbooks of pharmacology and poisoning suggest that promethazine, like all other phenothiazines, can produce acute dystonic reactions.[4] We found in the literature only one brief description of acute extrapyramidal manifestations caused by promethazine intoxication.[5]

Report of a Case.—A 2-year-old infant became lethargic after presumably ingesting promethazine syrup (Phenergan). An empty 240-mL bottle of the drug was found on the floor. She became unresponsive and difficult to arouse two to three hours later, and gastric lavage was performed about four hours after ingestion. This was associated with a brief respiratory arrest that responded to cardiopulmonary resuscitation. She gradually appeared to become less obtunded, but acute dystonic crises developed 24 hours after the ingestion of promethazine. Diphenhydramine hydrochloride (Benadryl) was given at that time to treat her oculogyric crises. She received 50-mg doses administered intravenously an hour apart, without effect. Twenty-eight hours after ingestion, the acute dystonic crises appeared to worsen, occurring every 30 to 60 s, with each episode lasting 15 to 20 s. Each would begin with a shrieking cry, followed by extension of the head and adversive head and eye turning, usually to the right side. This ocular turning was not obligate, since a positive response to the opposite side occurred when oculocephalic maneuvers were performed during the crisis. The defensive blinking to a visual threat during these episodes and the absence of pupillary dilation would indicate that this was not a convulsion. The left elbow was flexed and the right extended. She remained alert after these periods. As these dystonic movements subsided, stereotyped tongue-darting movements with lip smacking and repetitive sucking would continue for 5 to 10s. The crises ceased five hours after onset. Forty-eight hours after the ingestion, she was alert and her speech was normal. Her peripheral-muscle tone was increased and she had bilateral Babinski's signs that had resolved on subsequent follow-up examination after discharge.

A urine sample taken 28 hours after ingestion was assayed by the method of alkaline extraction followed by gas-liquid chromatography. It confirmed the presence of promethazine. An EEG performed 48 hours after the ingestion was normal.

Comment.—Previous reports of intoxication with promethazine described a total of five children, ranging in age from 5 to 11 years.[5-8] A depression in the state of conscious-

ness, generalized convulsions, and incoherence of speech were the commonly described effects of therapeutic doses on CNS function. In one case reported by Swaiman,[5] the patient had opisthotonic crises that resolved spontaneously. Twenty-eight hours after ingestion of promethazine, she was noted to have rhythmic jaw movements and coma. Our patient showed depression of the state of consciousness at the onset. The acute excitomotor manifestations developed as she became more alert. This is typical of intoxication with antihistaminic drugs.[2] However, oculogyric crises and orobuccolingual dyskinesias have not been described with anihistaminic agents.

The mechanism of such dystonic reactions is presently unclear. Some involuntary movements seen in acute dystonias resemble those occurring with chronic antipsychotic phenothiazine-induced tardive dyskinesia. It has been suggested that tardive dyskinesia may be a result of drug-induced supersensitivity of dopamine receptors after prolonged blockade.[2] The action of promethazine in the rat model differs from the antipsychotic phenothiazines and produces no change in the turnover of central dopamine hydrochloride.[9] But, in addition to its antihistaminic action, promethazine possesses considerable antiserotonin action, similar to LSD.[10]

It is possible that drug-induced dystonic reactions are a result of dopaminergic, cholinergic, or serotonergic blockade. The occurrence of acute dystonic crises, whether with antipsychotic phenothiazines or, as in our case, with promethazine, suggests that the mechanisms of production of acute reactions is different than that in tardive dyskinesia.

Drug-induced acute dystonic crises have been treated with various agents successfully, including diphenhydramine and benztropine mesylate. Fisher[6] used intramuscular diphenhydramine unsuccessfully to treat promethazine-induced combativeness, disorientation, and incoherence of speech in a child. He blamed the lack of response on the intramuscular route of administration. Our patient received intravenous diphenhydramine in adequate doses, with no apparent response. We did not use benztropine, since the rate of occurrence of the dystonic attacks appeared to be subsiding. Some authors suggest supportive management only, except if the patient's condition deteriorates.

Simultaneous Microangiopathic Hemolytic Anemia, Thrombocytopenia, and Acute Nephropathy in Mother and Child

Microangiopathic hemolytic anemia, thrombocytopenia, and acute nephropathy are hallmarks of the hemolytic-uremic syndrome (HUS).[1] Though there have been reports of HUS occurring in families,[2-6] we are unaware of previous reports of microangiopathic hemolytic anemia, thrombocytopenia, and renal failure occurring simultaneously in parent and child.

Report of Cases.—CASE 1.—A 31-year-old woman had been well until diarrhea and abdominal pain developed. Three days later, her stools became bloody, and she was admitted to the hospital.

Her initial hematocrit reading was 52%, and a few schistocytes were seen on blood smear. Platelets appeared adequate in number. The urine was concentrated, had ketones, but was otherwise normal. Her BUN and serum creatinine concentrations were 5.0 and 0.9 mg/dL, respectively. On the third hospital day, she became febrile, numerous purpuric lesions developed, and she became confused and lethargic. The platelet count fell to 40,000/cu mm, and the peripheral smear showed increased numbers of schistocytes. The hematocrit reading decreased rapidly, and several blood transfusions were given. The serum fibrinogen level was normal, but her serum tests were positive for fibrin split products. Her CSF was normal, blood cultures showed no growth, and no pathogens grew in stool cultures. A presumptive diagnosis of thrombotic thrombocytopenic purpura (TTP) was made, and she was treated with daily infusions of frozen plasma, dipyridamole, aspirin, and methylprednisolone (800 mg/12 hr). Two days later, she became anuric and comatose; frequent grand mal seizures developed, and ventilation therapy was begun. The following day, hemodialysis was begun, and fresh frozen plasma and platelet infusions were continued daily.

She remained comatose, thrombocytopenic, and anuric throughout the remainder of her hospitalization. Hemodialysis and artificial ventilation were continued, but the adult respiratory distress syndrome developed on the 18th hospital day, and she died ten days later. At autopsy, fibrin thrombi were found in the vessels of her kidney. A few scattered thrombi were also seen in her lung vessels, but the heart, intestines, stomach, liver, lymph nodes, adrenal glands, ovaries, and spleen were free of thrombi. The brain was not examined.

CASE 2.—The 4½-year-old son of patient 1 had cramping abdominal pain and bloody diarrhea the same day his mother became ill. The abdominal pain and bloody diarrhea persisted, and three days later he was admitted to the hospital.

The hematocrit reading was 40%, platelets appeared to be adequate in number, but occasional schistocytes were seen. His urinalysis results were normal, and the BUN concentration was 11 mg/dL. The cramping abdominal pain decreased substantially, though the bloody diarrhea continued. No pathogenic organisms grew in stool cultures, however.

A complete blood cell count done four days later revealed that the hematocrit reading had dropped to 15%, the serum hemoglobin level, to 5.0 g/dL, and the

platelet count, to 47,000/cu mm. His peripheral smear showed substantial numbers of schistocytes and occasional burr cells. The BUN concentration had increased to 49 mg/dL, and the urinalysis showed a trace of protein, RBCs (eight to ten per high-power field [HPF]), WBCs (five to ten per HPF), and casts (three to five per HPF). The child was transfused with packed RBCs. Three days later, the platelet count was up to 143,000/cu mm, the hematocrit reading was stable at 23%, and the BUN concentration was down to 13 mg/dL. He was discharged the following day. When seen in follow-up six months later, the child's hematocrit reading was 34%, the urinalysis results were normal, and the serum creatinine concentration was 0.7 mg/dL.

Comment.—Patients with HUS and TTP have many features in common. The enteritis, microangiopathic hemolytic anemia, thrombocytopenia, and acute renal disease experienced by the child fulfilled the criteria for the HUS. While his illness was milder than average, a wide range of severity is recognized.[7] His mother's persistent thrombocytopenia, microangiographic hemolytic anemia, severe neurologic involvement, and renal failure were characteristic for TTP. Histologic confirmation of multiple organ involvement was not found, however, and the few thrombi in the lungs could have been secondary to the adult respiratory distress syndrome. Her illness might, therefore, best be described as a severe case of HUS.

The reason for the occurrence of this disorder in both mother and child is uncertain. The simultaneous occurrence in both suggests a common environmental cause. Three days before they contracted enteritis, bloody diarrhea developed in the 2½-year-old male sibling of patient 2. He was otherwise asymptomatic, however, and the diarrhea resolved spontaneously within six days. Laboratory studies performed five days later showed no proteinuria, hematuria, or anemia. Though a variety of pathogens have been recovered from the stools of some patients with HUS, no enteric pathogens ever grew in cultures taken from our patients. Viral studies were not performed, however. The possibility of a genetic predisposition cannot be excluded, but Kaplan et al have speculated that genetically predisposed cases of HUS in siblings are characterized by disease episodes occurring more than a year apart.[2]

The report of the simultaneous occurrence of a hemolytic-uremic type syndrome in mother and child, coupled with previous reports of occurrence in families,[2-6] should alert physicians to consider this diagnosis in family members who share a similar diarrheal prodrome.

Bilaterally Enlarged Testicles in a Newborn: An Atypical Presentation of Intrauterine Spermatic Cord Torsion

Torsion of the spermatic cord is a recognized surgical emergency at any age, but has peak incidence in the neonatal and adolescent pediatric age groups.[1] Perinatal unilateral torsion is well documented and the subject of a recent excellent review.[2] Bilateral intrauterine torsion of the spermatic cord, however, is a rare event—to our knowledge, only five cases have been reported.[3-7] We report a sixth case of intrauterine bilateral spermatic cord torsion with a markedly atypical presentation.

Report of a Case.—A 3,465-g full-term male infant was born to a 24-year-old, gravida 2, para 1, blood type O^+ mother after an uncomplicated pregnancy and labor. Meconium-stained amniotic fluid was observed at the time of vaginal delivery. There was no respiratory distress. Apgar scores were 6 at one minute and 9 at five minutes. Enlarged testicles were noted at delivery.

Physical examination revealed a full-term, appropriate for gestational age, male infant with a pendulous scrotum. There was no scrotal edema, swelling, puckering, or skin discoloration. The testes were enlarged bilaterally but not tender. The right testicle measured 1.5 × 2.5 cm (estimated volume, 2 mL). The left testicle measured 2.0 × 3.0 cm (estimated volume, 3 to 4 mL). Both testes were firm to palpation, slightly nodular, and did not transilluminate. The epididymis was located posteriorly bilaterally and the spermatic cords were of normal size. No other abnormalities were noted.

Laboratory results included a normal complete blood cell count and normal urinalysis results. Blood type was A^+ with a positive direct Coombs test for anti-A isoagglutinins. The serum bilirubin level was not elevated.

Consultations with specialists in pediatric oncology, endocrinology, genetics, urology, and pathology yielded many recommendations for additional laboratory tests. Electrolyte, T_4, and serum 17-OH-progesterone levels were normal. The serum testosterone level was 8 ng/dL (normal mean value, 68 ng/dL). A buccal smear was negative for Barr bodies. Karyotyping revealed a normal 46 XY chromosome pattern.

A scrotal roentgenogram showed no calcific densities. Doppler ultrasound examination of the testicular vessels revealed normal to slightly increased pulsations when compared with other male infants in the nursery. A technetium pertechnetate (Tc 99m) testicular scan indicated bilateral avascularity of the testes with a surrounding rim of increased uptake. The study was interpreted as consistent with tumor or bilateral torsion.

On the ninth day of life, reexamination revealed both testes to be slightly decreased in size (right, 1.9 × 2.2 cm; left, 2.0 × 2.6 cm). On the 11th day of life, the infant underwent surgical exploration of the scrotum and testicular biopsy. Dissection revealed inflamed, hemorrhagic tunicas and testes that appeared necrotic and atrophic. The right measured 1.2 × 0.7 × 0.8 cm and the left 1.5 × 0.7 × 0.8 cm. The diagnosis of bilateral extravaginal spermatic cord torsion was confirmed. Wedge biopsy specimens of both testes were obtained and the testes were repositioned in the scrotum; however, no improvement in blood flow was noted before closure.

Microscopic examination of the biopsy specimens showed the right testis to contain frank hemorrhagic necrosis with old pigment deposition of a chronic nature (Fig 1). The biopsy specimen from the left testis revealed markedly hemorrhagic tissue with many seminiferous tubules showing evidence of early hemorrhagic necrosis (Fig 2). These findings were consistent

with a disparity in time between torsion of the right and left testis, torsion of the right testis occurring first. Both torsions had occurred prior to birth.

Comment.—The present case is interesting in that the absence of acute local signs, ie, red or bluish skin discoloration, scrotal puckering, swelling, or edema, is an unusual presentation for testicular torsion. In addition, the right and left torsions appear to have occurred at different times in utero.

In light of the presumed torsion, the finding of good intrascrotal pulsations with a Doppler device was unexpected. Though arterial flow is usually decreased in torsion, increased Doppler pulsation has been reported in older patients with intravaginal torsion.[8] Whether a similarity in Doppler examination exists in patients with intravaginal and extravaginal torsion is not known. Technetium scanning of the testes is a relatively new but reportedly accurate method for evaluating testicular avascularity and has recently been advocated for use in young infants.[9] This method seems to provide a safe, rapid, and reliable adjunct to diagnosis. In the present case, a decrease in testicular perfusion was well demonstrated.

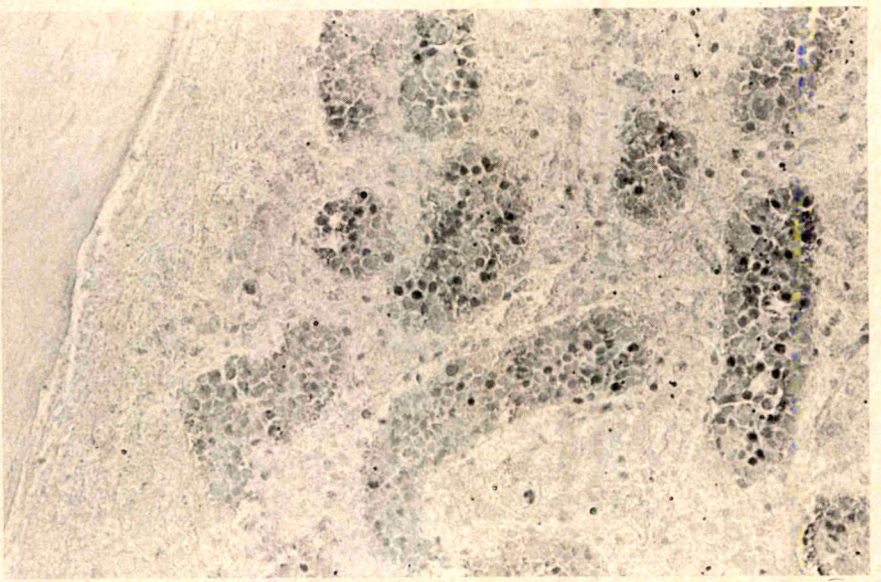

Fig 1.—Right testicular biopsy specimen. Hematoxylin-eosin stain reveals frank hemorrhagic necrosis of seminiferous tubules with hemosiderin deposition (×31.25).

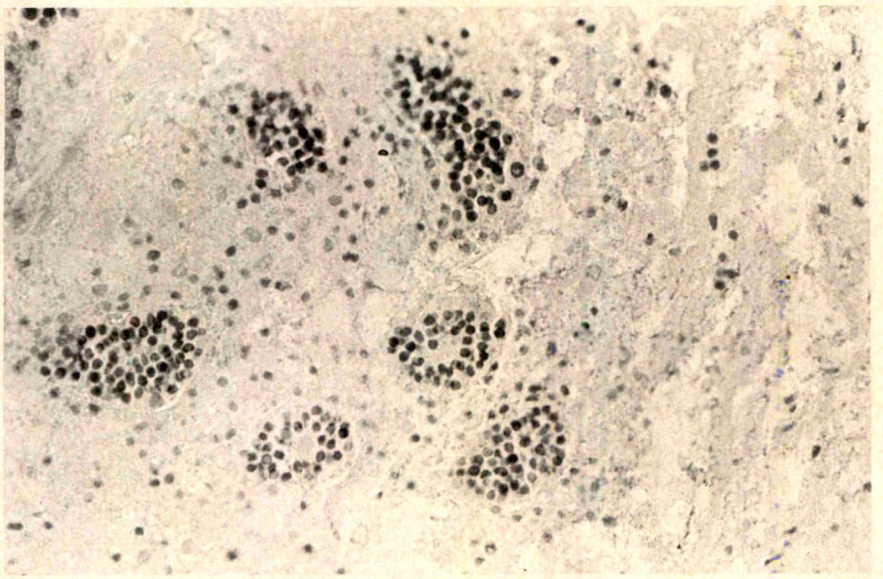

Fig 2.—Left testicular biopsy specimen. Hematoxylin-eosin stain shows marked hemorrhage with multiple seminiferous tubules evidencing early hemorrhagic necrosis (×31.25).

In comparing the present case with the five cases previously reported, it is noted that four of the six infants had either breech presentation, delivery by cesarian section, or presence of meconium at birth. All infants were asymptomatic. Five of the six infants had signs of acute torsion with scrotal swelling and skin color changes. Only three of 12 testes seemed to show reestablishment of some blood flow with surgical intervention. Of four cases where pathology reports are available, three show indications that right testicular torsion occurred at a time prior to torsion of the left side. This is particularly interesting, as left-sided torsion is more common in older patients. The predominance of right sided torsion preceding left may suggest a previously unrecognized etiological factor in extravaginal torsion.

Intrauterine bilateral spermatic cord torsion appears to represent a spectrum of disease. In earliest form, it occurs before or during testicular migration and results in childhood anorchia.[10] It may occur antenatally after migration (as in the present case), resulting in a lack of acute signs at birth. With occurrence at or near term, the more familiar signs of inflammation and ischemia will be present.

'Breech Head' With Brow Presentation

Recently, Haberkern et al[1] described a group of newborns with scaphocephaly and occipital shelving that were sufficiently disfiguring to generate parental and physician concern. On the basis of a consistent association with breech positioning in utero in their series, they designated this the "breech head" and attributed it to a postural deformation related to this position or to sharing a common etiology.[1] We describe here an infant born with a classic breech head who was born in brow presentation.

Report of a Case.—A full-term, 3,347-g female infant was born to a 27-year-old primigravida. The pregnancy had been uncomplicated except for conversion of tuberculin in the second month, with a normal chest roentgenogram. Isoniazid therapy had been started in the seventh month. At no time had there been evidence of oligohydramnios. Labor had begun spontaneously and had been prolonged (26.5 hours). Delivery was difficult due to a brow presentation, with Apgar scores of 7 and 8 at one and five minutes, respectively. In the delivery room, the infant was noted to be hypotonic, scaphocephalic, and was thought to have dysmorphic facies. Genetic and neurologic consultation was sought in the nursery. Family medical history was remarkable only for three infant deaths and one miscarriage among maternal relatives. Physical examination revealed a hypotonic infant in no acute distress. Head circumference was 37 cm (98%) with marked scaphocephaly and occipital shelving. All sutures were normal to palpation, the anterior fontanel measuring 3 × 2.5 cm. The face was edematous with a large ecchymosis on the forehead. The nose was deviated slightly to the left. The mild dysmorphic features consisting of dystopia canthorum, broad and high nasal bridge, slightly low-set ears with depression of the superior helix, and a high-arched palate with unusual alveolar ridges did not suggest a specific dysmorphic syndrome. Results of the remainder of the examination were within normal limits. Skull roentgenograms confirmed the clinical impressions, showing elongation and shelving of the occiput (Figure). The karyotype was a 46,XX female pattern with normal Q-banding. The infant's tone improved and she was discharged home on the seventh day of life without a specific diagnosis other than that of breech head. Follow-up at 3 and 6 months of age in our clinic revealed a large, well-developed female infant whose head shape had reverted to normal. Results of developmental screening and neurologic examinations were within normal limits.

Lateral skull roentgenogram at birth showing scaphocephaly and occipital shelving.

Comment.—The clinical appearance and roentgenograms of this infant with brow presentation are identical to those described with the breech head. Haberkern et al[1] remarked that they had not excluded the occurrence of this deformation in other presentations. In the present case, the subsequent normal development and resolution of the deformation agree with similar observations of the postnatal natural history of infants with the breech head. The hypotonia in the neonatal period here may be attributed to the prolonged, difficult labor, which possibly in turn was influenced by the deformation. It is not clear whether this resulted exclusively from the prolonged labor or is related in some common pathway for this deformation in breech and other presentations. However, the association of altered tone and activity in utero has been correlated with the breech position[2] and may suggest some etiologic factors in common with our case. The possible role of this deformation in birth injuries from difficult vaginal deliveries has been emphasized by the original researchers,[1] and one week after the birth of the present patient, we saw an infant with the breech head in breech presentation who suffered a partial seventh nerve palsy before cesarian section was performed.

We conclude that whereas the strongest correlation with this deformation is the breech position in utero, other modes of compression clearly may likewise result in the breech head. We concur strongly with Haberkern et al[1] that early recognition of this may avert substantial birth trauma.

Hematemesis and Melena in Infant

Gastrointestinal (GI) hemmorrhage may be a serious symptom but in the newborn infant hematemesis and melena may simply be due to maternal blood swallowed during birth.[1-4] We report a case of apparently serious intestinal bleeding in a 10-week-old infant that turned out to be innocent.

Report of a Case.—The baby was born normally at term weighing 3,200 g and had no problems. She was breast-fed from birth and additional cow's milk and orange juice had been introduced. At the age of 10 weeks, she was referred to our pediatric emergency room by her attending physician because of melena and coffee-ground vomiting during a period of several hours. Apart from some reduction in appetite, she was otherwise behaving normally. On examination, she was surprisingly healthy with no pallor, tachycardia, or any other abnormal physical signs. Nevertheless, while being examined she vomited a small amount of coffee-ground material and passed a black stool that was strongly positive when tested for blood. Her hemoglobin level was 11.9 g/dL and her complete blood cell count was normal.

Because of the discrepancy between the excellent condition of the infant and the obvious blood in her GI tract, a thorough review of the history was made. Her mother denied administering any drugs and said she had no problems in breast-feeding. She had breast-fed her two previous children. Later, she admitted that the previous night she had experienced some discomfort

in feeding the infant and had noticed a small amount of blood on her nipple. A few hours after this, the infant had had her first melena and coffee-ground emesis. Examination of the mother by the pediatrician showed a deep fissure in her left nipple. Feeding from the left side was stopped and during the day the baby stopped vomiting and her stools became normal.

Comment.—The lesson to be learned from this case is the importance of the discrepancy between the clinical state of the infant and the presence of large amounts of blood in vomit and stool. As far as we are aware, ingestion of maternal blood has not been reported as a cause of hematemesis and melena in infants beyond the immediate neonatal period.

Uridine Diphosphate Galactose 4-Epimerase Deficiency

In addition to the galactosemias associated with galactose-1-phosphate uridylyltransferase and galactokinase deficiency, uridine diphosphate (UDP) galactose 4-epimerase deficiency is a third disorder of galactose metabolism characterized by the inability to epimerize UDPgalactose and UDP-glucose. The first case was discovered during the course of newborn screening in Switzerland.[1] We would like to report observations on an infant whose condition was discovered in newborn screening and whose erythrocytes lack the capability to convert UDPgalactose to UDPglucose.

Patient and Methods.—The patient is the child of healthy parents. His blood was collected on filter paper for routine screening. Active uridyltransferase was indicated by the appearance of fluorescence in an enzyme spot screening test. The Paigen assay indicated a concentration of high levels of galactose and galactose-1-phosphate.[2,3]

At 3 months of age, he was referred to our hospital for the evaluation of the high level of galactose-1-phosphate in his blood. Epimerase activities were measured in heparinized blood from the infant, his parents, and adult control subjects by modifications of the method of Gitzelmann and Steinmann.[4] The blood galactose level was measured by the commercially available test combination based on oxidation by galactose dehydrogenase. The RBC galactose-1-phosphate level was measured by the same oxidation method with added alkaline phosphatase on filter-paper specimens. Galactose-1-phosphate uridylyltransferase activity was measured in a hemolysate by the UDPgalactose consumption method of Beutler and Baluda.[5]

Results.—Blood galactose-1-phosphate concentrations in the patient varied from 15 to 42 mg/dL during the first 7 weeks of life when he was receiving a lactose-containing formula. In our laboratory, the mean level of blood galactose-1-phosphate in 66 term infants at 5 to 7 days of life was 2.18 ± 1.55 mg/dL, with a range of 0 to 7.69 mg/dL. The normal range of blood galactose levels in neonates is 0 to 1.42 mg/dL.

At the age of 2 months, he was given an oral galactose tolerance test with 0.75 g/kg in 10% water. Blood galactose levels reached 11.0 mg/dL, and erythrocyte galactose-1-phosphate levels rose from 7.2 to 12.0 mg/dL after one hour. Epimerase activity in erythrocytes from the patient ranged between 0.076 and 0.310 μmole/hr/g hemoglobin.

The mean epimerase activity in the eight adults was 8.67 μmole/hr/g hemoglobin ±1.40 SD (range, 7.18 to 11.58 μmole/hr/g hemoglobin). The epimerase activities of his mother and father were 3.14 and 4.80 μmole/hr/g hemoglobin, respectively. He had normal activity of erythrocyte galactose-1-phosphate uridylyltransferase. No reducing substance was found in the urine. Results of his liver function tests were normal, and no cataracts or neurological manifestions were found.

After three months, he was fed with a formula containing less galactose, and his erythrocyte galactose-1-phosphate level was between trace and 5.0 mg/dL and fell to 0 mg/dL after galactose-free milk was instituted. His psychomotor development was normal at 1 year of age.

Comment.—The first case was discovered during a newborn screening program in Switzerland, and the patient's erythrocyte concentration of galactose-1-phosphate was found to be increased.[1] Eight persons in three different families are known to have no activity of UDPgalactose 4-epimerase in their circulatory blood cells.[6] Our data are in accordance with the findings of Gitzelmann et al[6] that led them to conclude that the epimerase-deficient state is a benign, inborn error of galactose metabolism.

There are no clinical or laboratory abnormalities in the epimerase-deficient person except for the slight increase of galactose and markedly increased concentrations of galactose-1-phosphate in peripheral blood. Lack of clinical findings is probably due to normal enzyme activities found in liver and some other tissues. Normal epimerase activities are found in cultured skin fibroblasts and stimulated lymphoblasts.[6] A correct diagnosis is mandatory to avoid unnecessary dietary treatment for the newborn infant with high levels of erythrocyte galactose-1-phosphate.

FELLOWSHIPS IN DEVELOPMENTAL PEDIATRICS

Two and three-year fellowships in Developmental Pediatrics are available at The John F. Kennedy Institute for January and July of 1981. This fellowship includes a six-month rotation through a forty-bed inpatient service and another six-month rotation through an active child patient service (child development clinic). In addition, rotations include pediatric neurology, child psychiatry, genetics and biochemical laboratory, EEG Laboratory, and neurosciences.

Candidates must have completed a three-year training period in pediatrics.

For further information write to Arnold J. Capute, M.D., M.P.H., Deputy Director, The John F. Kennedy Institute, 707 North Broadway, Baltimore, Maryland 21205.

JOIN US.

We can do much more together.

PEDIATRICIAN

La Rabida Children's Hospital and Research Center, affiliated with The University of Chicago, seeks a Board-certified pediatrician, preferably with a fellowship in ambulatory pediatrics or experience/interest in children with chronic diseases. Responsibilities include inpatient and outpatient services in a specialized chronic care pediatric hospital of 73 beds with approximately 8,300 outpatient visits annually. An academic appointment of appropriate rank will be made in the Department of Pediatrics of The University of Chicago, an equal opportunity employer. Inquiries and CV should be directed to: Search Committee, La Rabida Children's Hospital and Research Center, 65th Street at Lake Michigan, Chicago, Il 60649.

Ilosone® (erythromycin estolate)

WARNING

Hepatic dysfunction with or without jaundice has occurred, chiefly in adults, in association with erythromycin estolate administration. It may be accompanied by malaise, nausea, vomiting, abdominal colic, and fever. In some instances, severe abdominal pain may simulate an abdominal surgical emergency.

If the above findings occur, discontinue Ilosone promptly.

Ilosone is contraindicated for patients with a known history of sensitivity to this drug and for those with pre-existing liver disease.

Indications: *Streptococcus pyogenes* (Group A Beta-Hemolytic) – Upper and lower respiratory tract, skin, and soft-tissue infections of mild to moderate severity.

Injectable penicillin G benzathine is considered by the American Heart Association to be the drug of choice in the treatment and prevention of streptococcal pharyngitis and in long-term prophylaxis of rheumatic fever.

When oral medication is preferred for treating the above-mentioned conditions, penicillin G or V or erythromycin is the alternate drug of choice.

The importance of the patient's strict adherence to the prescribed dosage regimen must be stressed when oral medication is given. A therapeutic dose should be administered for at least ten days.

Alpha-Hemolytic Streptococci (Viridans Group) – Short-term prophylaxis against bacterial endocarditis prior to dental or other operative procedures in patients with a history of rheumatic fever or congenital heart disease who are hypersensitive to penicillin. (Erythromycin is not suitable prior to genitourinary surgery when the organisms likely to lead to bacteremia are gram-negative bacilli or belong to the enterococcus group of streptococci.)

Staphylococcus aureus – Acute infections of skin and soft tissue which are mild to moderately severe. Resistance may develop during treatment.

S. (Diplococcus) pneumoniae – Infections of the upper respiratory tract (e.g., otitis media, pharyngitis) and lower respiratory tract (e.g., pneumonia) of mild to moderate severity.

Mycoplasma pneumoniae (Eaton Agent, PPLO) – Respiratory tract infections due to this organism.

Haemophilus influenzae – May be used concomitantly with adequate doses of sulfonamides for upper respiratory tract infections of mild to moderate severity. Not all strains of this organism are susceptible at the erythromycin concentrations ordinarily achieved.

Treponema pallidum – As an alternate treatment in penicillin-allergic patients. In primary syphilis, spinal-fluid examinations should be done before treatment and as part of follow-up after therapy.

Corynebacterium diphtheriae – As an adjunct to antitoxin, to prevent establishment of carriers, and to eradicate the organism in carriers.

C. minutissimum – In the treatment of erythrasma.

Entamoeba histolytica – For intestinal amebiasis only. Extra-enteric amebiasis requires treatment with other agents.

Listeria monocytogenes – Infections due to this organism.

Legionnaires' Disease – Although no controlled clinical efficacy studies have been conducted, in vitro and limited preliminary clinical data suggest that erythromycin may be effective in treating Legionnaires' disease.

Contraindication: Known hypersensitivity to this antibiotic.

Warnings: (*See* Warning box above.) The administration of erythromycin estolate has been associated with the infrequent occurrence of cholestatic hepatitis. Laboratory findings have been characterized by abnormal hepatic function test values, peripheral eosinophilia, and leukocytosis. Symptoms may include malaise, nausea, vomiting, abdominal cramps, and fever. Jaundice may or may not be present. In some instances, severe abdominal pain may simulate the pain of biliary colic, pancreatitis, perforated ulcer, or an acute abdominal surgical problem. In other instances, clinical symptoms and results of liver function tests have resembled findings in extrahepatic obstructive jaundice.

Initial symptoms have developed in some cases after a few days of treatment but generally have followed one or two weeks of continuous therapy. Symptoms reappear promptly, usually within 48 hours after the drug is readministered to sensitive patients. The syndrome seems to result from a form of sensitization, occurs chiefly in adults, and has been reversible when medication is discontinued.

Usage in Pregnancy – Safety of this drug for use during pregnancy has not been established.

Precautions: Caution should be exercised in administering the antibiotic to patients with impaired hepatic function.

Recent studies of erythromycin reveal that its use in patients receiving high doses of theophylline may be associated with an increase in serum theophylline levels and potential theophylline toxicity. In such a case, the dose of theophylline should be reduced while the patient is receiving concomitant erythromycin therapy.

Surgical procedures should be performed when indicated.

Adverse Reactions: The most frequent side effects are gastrointestinal (e.g., abdominal cramping and discomfort) and are dose related. Nausea, vomiting, and diarrhea occur infrequently with usual oral doses.

During prolonged or repeated therapy, overgrowth of nonsusceptible bacteria or fungi is possible. If such infections arise, the drug should be discontinued and appropriate therapy instituted.

Mild allergic reactions, such as urticaria and other skin rashes, have occurred. Serious allergic reactions, including anaphylaxis, have been reported. [013079]

Letters to the Editor

Correspondence pertaining to material published in the JOURNAL will be published, if found suitable, as space permits. Submit double-spaced copy clearly marked "For publication" and signed by all authors; references should conform to JOURNAL format; maximum length: 500 words. Copyright assignment signed by all authors is required. The Editor reserves the right to edit such letters, which should be received within six weeks of publication of the JOURNAL article in question.

Abdominal Pain

Sir.—I would like to comment regarding Dr Lebenthal's article "Recurrent Abdominal Pain in Childhood" (JOURNAL 134:347-348, 1980). As a clinician, I am repeatedly distressed to find that so many physicians who discuss abdominal pain find solace in the medical scrap basket called psychosomatic illness. I am sure that such problems are at times psychosomatic, but I believe that this diagnosis is made too frequently to mask our own inadequacies in diagnosis. The literature has shown repeatedly that foods can cause dramatic, observable effects on the gut and that these problems are real.[1-8] Not all food-related reactions are IgE-mediated. The fact that a physician cannot always understand *why* a food causes symptoms cannot be equated to the fact that a food *does* cause symptoms. Unfortunately, although careful clinicians see many children who respond favorably to dietary manipulation, scientific documentation is not always possible or practical. Parents who have been told repeatedly that they must accept their child's illness as nonorganic are grateful and relieved when they finally find a physician who readily eliminates the child's chronic intestinal problems within a few days by placing the child on a simple diet. Parents, however, are not so grateful that they want to be responsible for causing their children to have abdominal discomfort again merely to prove to some skeptical physicians that their child's medical problem was real. I do not think the parents can be faulted for this attitude.

In my experience, children who have dark circles about and puffiness under their eyes, a positive family and personal history of classic allergy, and recurrent abdominal pain often have a food-related problem. The symptoms frequently have started early in infancy with repeated formula changes, colic, inability to sleep, and repeated otitis. Affected children are often worse after parties or holidays; they are as ill on weekends as they are on school days, and many are better during the summer months. The latter is typical of some types of food-related allergies. Affected children often have associated chronic leg aches, muscle aches, enuresis, rhinorrhea, and activity, learning, and behavioral problems. These complaints are not psychosomatic; if left undiagnosed for many years, however, such problems surely arise on a secondary basis. This entity is Speer's[9] classic allergic-tension-fatigue syndrome. Unfortunately, this pediatric stepchild is often unsuspected or not diagnosed. A simple diet excluding the major highly allergenic foods for a week often relieves *all* of these symptoms, and by challenging the child with one food at a time during the second week, the individual symptoms often can be reproduced.[10] The relieving diet usually consists of meat (no bacon, ham, or luncheon meats), most fruits, and most vegetables (no corn). The diet excludes the major food offenders: milk, corn, sugar, wheat, eggs, chocolate, food coloring, food additives, and food preservatives. Somewhat less frequent offenders include orange juice, peanut butter, tomato, apple, and grape.

We live in an era of drug-oriented medicine. Maybe it is time we started to listen to parents, to seriously consider their observations, and to realize that what we put into the gastrointestinal tract could, conceivably, adversely affect any area of the body.[11]

Mortality and Sex Difference

Sir.—In a recent article entitled "Immunological Bases for Superior Survival of Females" (JOURNAL 133:1251-1253, 1979), Purtilo and Sullivan presented evidence for superior immunocompetence of females and hypothesized that this contributes to the greater longevity of females. It is useful to consider their argument in the context of a more comprehensive analysis of the causes of sex differences in mortality.[1]

In the contemporary United States, sex differences in mortality due to infectious diseases account for only about 4% of the total sex difference in mortality (based on age-adjusted death rates calculated from data in *Vital Statistics of the United States*[2] using methods described by Waldron[1]). Sex differences in mortality due to neoplasms account for an additional 14% of the total sex difference in mortality. It is unclear how much of this difference may be due to sex differences in immunocompetence. It should be noted that malignant neoplasms of the respiratory system alone are responsible for 11% of the total sex difference in mortality, and it is clear that in this case sex differences in cigarette smoking habits make a major contribution to the sex differences in mortality.[1-3]

Forty-one percent of the total sex difference in mortality is due to ischemic heart disease. Previous analyses have presented evidence that men's higher rates of ischemic heart disease are due in large part to greater cigarette smoking by men,[1,3,4] a greater prevalence of the hard-driving "Type A" or Coronary-prone Behavior Pattern among men,[1,4,5] and possibly also to the effects of sex hormones.[1,4,6]

Other causes of death that contribute to the sex difference in mortality include accidents (11% of the total difference), homicide and suicide (5%), and emphysema and cirrhosis of the liver (5%). In each case, sex differences in behavior make a substantial contribution to the sex differences in mortality.[1]

There is considerable cross-cultural and historical variation in the sex differences in mortality.[1,4,7] For example, in the United States, the sex difference in life expectancy was eight years in 1970, but only two years in 1920.[1] Analyses of the historical and cross-cultural variation have provided further evidence that behavioral and cultural factors make a major contribution to sex differences in mortality.[1,4,7]

In conclusion, although sex differences in immunocompetence probably contribute to sex differences in mortality, the available evidence indicates that sex differences in behavior make a substantially larger contribution to sex differences in mortality in the contemporary United States.

Reye's Syndrome

Sir.—I read with interest the article in the JOURNAL (133:1009-1013, 1979) by Baliga and co-workers, who described three patients with Reye's syndrome associated with disseminated intravascular coagulation (DIC) and acute renal failure. The authors emphasized the importance of initial and continuing evaluation of renal function in Reye's syndrome, especially in patients receiving osmotic diuretic therapy.

I would like to stress another point. All patients received fresh frozen plasma because of a severe coagulopathy compatible with DIC. The coagulopathy did not improve after administration of the coagulation factors and, subsequently, exchange transfusions were done. Thrombocyte counts were near normal on admission to the hospital but decreased during the course of the disease.

Administration of plasma and plasma products, in particular prothrombin complex concentrates, can induce or accentuate DIC with liver disease.[1-5] In 1977, Grubbauer and I described an infant with severe Reye's syndrome in whom DIC and renal failure also developed.[6] This patient was admitted to our hospital with a normal thrombocyte count. Because of the prolonged prothrombin time, a prothrombin complex concentrate was administered. Subsequently, the platelet count dropped to low levels, and coagulation studies showed signs of severe DIC. At this point, the infant was heparinized, and the coagulation profile gradually returned to normal. However, renal dysfunction persisted, and a fatal outcome could not be averted.

Administration of coagulation factor-containing material to patients with Reye's syndrome should be done cautiously and with careful monitoring of clotting tests. If signs of hypercoagulability or DIC develop or persist, judicious use of heparin should be considered. In certain cases of liver disease associated with DIC, heparin has been demonstrated to be of benefit.[1,4]

Genetic Implications of Ultrasonographic Detection of In Utero Cystic Hygroma

Sir.—In a recent RADIOLOGICAL CASE OF THE MONTH (JOURNAL 134:311-312, 1980), a cystic nuchal mass interpreted as a hygroma was detected by ultrasonography in a fetus of 28 weeks'

gestation. The full implications of the antenatal detection of hygroma by ultrasonography should be emphasized.

Chromosomal anomalies are probably responsible for a high percentage of spontaneous abortions and fetal deaths.[1] Cystic hygroma of the back of the neck is responsible for the webbed neck seen in stillborn and newborn infants with XO karyotypic Turner's syndrome. The appearance of the stillborn infant illustrated in the aforementioned case is strongly suggestive of that diagnosis.[2] The cleft lip/palate not associated with hygroma described in the previous stillborn infant also may be seen in Turner's syndrome, but neither those findings nor hygroma are sufficient to make that diagnosis in the absence of other pathologic findings or a karyotype. The posterior hygroma should also be distinguished from the more common anterolateral and often unilateral hygroma colli, which may be present at birth as an isolated lesion. The history of prior abortion and two stillbirths in the report suggests the possibility of a recurrent syndrome associated with fetal wastage, such as the familial nuchal bleb syndrome described in a karyotypically normal abortus.[3]

We suggest that abnormalities detected by ultrasonography be corroborated and extended by definitive cytogenetic and pathologic studies of aborted or stillborn infants. Supported by definitive information from combined studies, the physician may knowledgeably counsel the parents concerning past and future pregnancies.

Birth Defects original article series, New York, Alan R Liss Inc, 1979, vol 15, No. 5A, pp 51-61.

In Reply.—We agree with Drs Rutledge and Haas that Turner's syndrome has to be ruled out in a patient with evidence of hygroma. We raised the possibility of Turner's syndrome in our report and recommended amniocentesis because of the increase of α-fetoprotein in the fluid of fetuses with Turner's syndrome, though some believe that this is due to obtaining fluid from the cervical sac rather than from amniotic fluid.

As far as genetics is concerned, a majority of patients with Turner's syndrome are 45,X. However, 20% to 30% have various types of mosaicism including X/XX, X/XY, and X/XX/XY, or structurally altered chromosomes, such as an isochromosome X, ring X, or partial deletion of the X chromosome. No chromosomal analysis of amniotic fluid was done on our patient. A chromosomal study was attempted in the stillborn infant, but due to maceration of the fetal tissue the study was not successful.

Advertising Condoms

Sir.—The article, "Condoms for Sexually Active Adolescents" by Bergman (JOURNAL 134:247-249, 1980), deserves some comments. Advertising in the public media via television, radio, newspapers, and magazines may arouse the curosity of preteenagers unnecessarily and contribute to sexual activity in this age group. Advocating sexual responsibility and downplaying sexual activity before marriage may be a better way to prevent disease and unwanted pregnancies. If you really want to reach the teenagers, why not have condom dispensers in the boys' and girls' washrooms in the high schools? This would eliminate the embarrassment of buying condoms over the counter in drug stores and ensure availability for sexually active adolescents at a nominal price. I can well imagine the typical school board's and parents' response!

GILBERT A. FRIDAY, MD
3520 Fifth Ave
Pittsburgh, PA 15213

Sir.—In his article, Bergman has some persuasive arguments for encouraging the use of condoms by sexually active adolescents. I would, however, take issue with his approach. He advocates mass advertisement of condoms on television and radio and in newspapers and magazines. Does this mean that when you "go for the gusto," you reach for a condom or that two Wheaties box tops will get you a rubber? Probably not. However, the American advertising industry can take an item like a condom, glorify it, strip it of its moral implications, and make it as necessary for every teenager as underarm deodorant.

We believe that this mass-media approach implicitly establishes a moral standard and legitimizes teenage sexual activity. Dr Bergman states, "by advocating condom usage to those who are already sexually active, the physician does not condone promiscuity." This is, of course, true; but what about sexually inactive adolescents, and the parents who attempt to rear teenagers with sexual restraint? Might this not be an additional pressure similar to pornographic literature and movies?

Our alternative would be to zero in on the target group rather than the teenage populace at large. This could begin with general education programs in the schools, followed by distribution in commercial outlets that are keyed to the subculture of sexually active teenagers.

We agree that we must take tangible steps to mitigate the problem of teenage pregnancies and venereal disease. At the same time, let's not neutralize our moral principles so as to make "promiscuous" an obsolete word.

EDWARD J. FEROLI, MD
GORDON W. MELLA, MD
Department of Child Health
and Development
George Washington University
Medical School
901 23rd St NW
Washington, DC 20037

In Reply.—The concerns expressed by Drs Feroli and Mella are legitimate and well stated. It is possible that certain types of sensational contraceptive advertising might tempt previously chaste youngsters to "cross the line." It is hard for me to imagine, however, how ads for contraceptives could be any more "suggestive" than the material that currently saturates our television and movie screens. It has been repeatedly shown that

knowledge about sexuality does not alter sexual behavior.[1] The vast majority of youngsters who come to physicians' offices and family planning clinics inquiring about contraception are already sexually active.[2] Where is the target group that is sexually active? Assuredly not restricted to poor ghetto areas, but in my experience, omnipresent.

I agree with Dr Friday that we must continue to advocate sexual responsibility, but won't he cede, given that one of ten teenagers are becoming pregnant, that some different tack is needed? Pounding the pulpit harder is not going to do the job.

Whatever our thoughts about availability of contraceptives, cannot all members of the medical profession agree on the goal of reducing teenage pregnancies? If so, we should all support health education programs from kindergarten through 12th grade that stress responsible family life. I do not blame parents or school boards for banning discussions of human sexuality if physicians do not point out the costs of such a "head-in-the-sand" attitude. For my part, since a means is at hand to prevent numerous cases of hyaline membrane disease, sudden infant death syndrome, child abuse, and wretched parenting, I want at least to make the effort.

Spondylohypoplasia, Arthrogryposis, and Popliteal Pterygium

Sir.—We read with interest the report of Turkel et al in the JOURNAL (134:42-45, 1980) on a malformation complex that included spondylohypoplasia, arthrogryposis, and popliteal pterygium. We recently evaluated the condition of a male infant with the same characteristics. We believe that our description will add some observations to the already described anomalies and assist in recognition of this new malformation complex.

Report of a Case.—A term, male infant was born by cesarean section to a 22-year-old gravida 2, para 2, Puerto Rican mother. The father is a 23-year-old Puerto Rican. The marriage is nonconsanguineous. Their first child is a healthy 2½-year-old boy. There was no history of illness or drug ingestion during pregnancy. The birth weight was 2.830 g.

At birth the following features were noted: head hyperextension, wide anterior fontanel, faint frontal nevus flammeus, mild ocular proptosis, palpebral ptosis, high-arched palate, short neck, arthrogryposis, bilateral incomplete palmar simian creases, finger knuckle crease absence, short trunk, protuberant abdomen, discrete umbilical hernia, lordosis, hip abduction absence, popliteal pterygium, overlapping second toes, and rocker bottom feet.

At age 3 days, the infant had several brief episodes of cyanosis and tachycardia, tachypnea with a single snappy second heart sound, and hepatomegaly developed. The ECG showed sinus tachycardia, right deviation of the QRS axis, and upright T waves over the right precordial leads. The chest roentgenogram showed numerous vertebral anomalies, abnormal orientation of ribs, cardiomegaly, and normal pulmonary vascularity.

Treatment with digoxin and oxygen resulted in marked improvement. At age 14 days, his second heart sound was narrowly split but the ECG showed the same characteristics. At age 3 months, the cardiac auscultation and the ECG were entirely normal.

Comment.—A delay in the fall of pulmonary vascular resistance and pressure (probably enhanced by the thoracic deformity) precipitated cardiac insufficiency in this baby. As soon as the pulmonary hemodynamics improved, all the abnormal cardiovascular findings disappeared. We believe that these constellations of anomalies are gaining validity as a new syndrome.

'Fever Phobia'

Sir.—Dr Barton Schmitt's excellent article "Fever Phobia" in the February JOURNAL (134:176-181, 1980) is must reading for medical students and house officers, as well as a good reminder for practitioners. His guidelines might be improved on by initiating the discussion of fever with parents at the infant's first diptheria toxoid, pertussis vaccine, tetanus toxoid injection, rather than at the 4- or 6-month visit. Over the past 25 years I have found this a most opportune time to begin the "desensitization" program.

Child Abuse

Sir.—We find interesting comparisons between the data of Ellerstein and Canavan (JOURNAL 134:255-257, 1980) and the experience of our institution's Child Protection Committee. The committee reviews cases of all patients seen at Oklahoma Children's Memorial Hospital, Oklahoma City, who are suspected of being abused, regardless of their initial complaint. Thus, in contrast to the study population of Ellerstein and Canavan, ours includes patients first seen with complaints often entirely unrelated to sexual abuse.

Our overall proportional experience with cases of male sexual abuse is similar to theirs. From January 1977 through February 1980, the committee reviewed 59 cases of suspected sexual abuse, 13.6% of which were boys with a mean age of 7.4 years (range, 3 months to 13 years). However, none of the perpetrators were strangers to the male victims and only 12.5% of the males demonstrated any injuries on physical examination. This contrasts with values of 56% and 50%, respectively, in their study. All of our males were first seen with the chief complaint of sexual abuse, as were theirs.

These figures imply that many cases of sexual abuse of boys are being missed by the medical community due to a low index of suspicion and the difficulty in detecting signs of sexual abuse during examination of the male child. In view of the fact that from 44% to 100% of the perpetrators are known by the victims, it would seem likely that many cases are not first seen with the chief complaint of sexual abuse. In our population, 67% of the female victims come with complaints unrelated to sexual abuse and, assuming comparability with the proportion of male cases that are not reported by the family, at least a third of all male cases, and probably more, remain undetected. We strongly believe that further studies of large

numbers of cases are needed to (1) determine those historical factors that might prompt the physician to perform a more thorough search for physical signs of sexual abuse, and (2) determine what subtle physical signs, if any, are associated with sexual abuse.

Ellerstein and Canavan are to be commended for focusing attention on this problem. A high index of suspicion and a careful examination for physical signs might pick up many cases that at present are being missed.

Human Milk

Sir.—The results and conclusion of a recent report on cells and aqueous component of human milk by Gene L. France and associates require comment (JOURNAL 134:147-152, 1980).

It has been documented that human milk cells are functionally competent.[1,2] They are capable of ingestion and killing of microorganisms.[1,2] The aqueous component, on the other hand, is complementary to the cells in providing opsonins.[2] In addition, we have demonstrated that the milk cells are capable of reducing nitro blue tetrazolium.[3,4] Using the colostric leukocytes, this has been confirmed by France et al. The latter investigators, however, have reported a lack of chemotactic factor or factors in aqueous milk and a lack of chemotactic migration capacity by milk cells. We recently determined (using a modified Boyden's technique[3,4]) that milk cells obtained from 20 lactating women were capable of chemotactic migration in response to chemotactic factor or factors, and in the absence of chemotactic factors they exhibit random migration.[3,4] The aqueous component revealed chemotactic factor or factors that were partially heat labile.[4] The mean (±SD) chemotactic index (49 ± 19) of milk cells in response to activated serum was, however, less than (74 ± 25) that of blood neutrophils obtained from the same group of lactating women.[3,4] The results were similar with chemotactic factors obtained from *Escherichia coli*. The random migration of milk cells, in contrast, was more than that of blood neutrophils.[3,4]

It is difficult to account for the differences between our observations and theirs, especially in the absence of their actual results. They have used a different method[5] (agarose gel method) from ours,[3,4,6-8] but this is unlikely to be the only basis.

Their article does not include details of methodology such as day-to-day variation, variation of duplicate determinations, and confidence limits of the technique. Results obtained on the blood cells and milk cells have also been omitted. The control subjects (donors of blood cells) and the study subjects (milk donors) were also not well defined. The adverse effects of systemic infection,[9] diabetes, alcohol ingestion, and medications including aminoglycosides[8] on neutrophil chemotaxis are well known. Whether these factors were excluded in the study of the subjects was unstated. The neutrophils of the same lactating women, as measured in our study,[4] might have been a more appropriate control.

Based on our studies, we believe that milk cells are capable of chemotactic and random migration and that human milk has chemoattractive capacity. The latter may be a basic mechanism accounting for migration of blood cells in breast alveoli. In the absence of documentation, the conclusions of France et al appear unwarranted.

In Reply.—Dr Khan and his associates call attention to one aspect of neutrophil function, ie, chemotaxis, that we agree may be an important factor in host defense both for the mother in preventing breast abscesses and for the infant in providing neutrophils for antigen processing. Unfortunately, we have already imposed on the JOURNAL by submitting an unusually lengthy article and so omitted details of this particular assay. We chose to focus on data more specific to *Salmonella* infection.

Methods for chemotaxis under agarose were identical to those previously published[1] except that we quantitate the migrating cells with a micrometer disk (scale, 5 mm/100 units, type 9) eyepiece grid. After counting cells on the chemotactic side and control side of the neutrophil well, the chemotactic index is calculated using the following formula: chemotactic index (CI) = No. of cells on the chemotactic side/No. of cells on the control side. Our control values for peripheral blood neutrophils are 5.22 ± 1.89 (SD). Samples of colostrum and breast milk neutrophils from our 60 donors never demonstrated a CI greater than 1.3.

We have performed chemotactic assays in postpartum women and have found them to be no different from random control subjects; therefore, we found it unnecessary to draw blood from lactating women for these studies. Milk donors were healthy women not receiving medications and without systemic disease known to affect chemotaxis. We were careful in this selection since we were well acquainted with the literature referred to by Dr Khan.

Unfortunately, we are unable to comment on technical details that

might account for the findings of Khan et al since this work has only been published in abstract form.[2] We look forward to reading the forthcoming article.[3]

Suffice it to say that the two assays present quite different methodology, and this could certainly account for the discrepant results in question. There are many explanations, but we might offer this one. Increased neutrophil adherence in breast-milk leukocytes might decrease chemotaxis with the under agarose method (done on plastic plates) while not affecting measurement with the Boyden's chamber.

Previous investigators have demonstrated that the under agarose assay is more sensitive than the Boyden's one,[1] and we therefore chose the former methodology. We are also concerned with the high CI for the medium control reported by Khan et al.[2] Perhaps other readers of the JOURNAL have additional experience examining chemotaxis of breast-milk cells.

Neonatal Scabies

Sir.—The article by Burns et al, "Neonatal Scabies" (JOURNAL 133:1031-1034, 1979), is timely and achieves the stated goal of acquainting the reader with the observation that neonatal scabies has a different appearance than does scabies in older patients. However, some of their observations and statements are contrary to our experience.

The statement was made that the burrow of scabies is seldom seen in today's adult scabies and is rarer in infants and children. We have observed the burrow usually to be present in all ages, though often in altered form in infants. Examination of suspected scabietic patients must be meticulous. Adults may have as few as one or two burrows, which may be found in nondermatitic, nonpruritic areas. Burrows in children are often located on the palms, soles, and/or creases of the wrist. Casual inspection of the minute linear scale of a curved burrow may result in the incorrect conclusion that this represents merely the edge of an erosion or unroofed vesicle. In infants, the burrow is often altered by the pyodermic response. The clue is a linear arrangement of vesicles and/or pustules, which may be surmounted by an interrupted, fine linear scale. Identification of a burrow is very important, as this is the site of the mite, demonstration of which establishes the correct diagnosis. We do not abandon the search for the diagnostic burrow without a thorough and time-consuming examination.

Burns et al stated that the scabies mite survives only a few hours away from a human host. Thus, they did not recommend changing or laundering bedclothes or linen. Though survival time of the adult female mite has not been established, most estimates are in the one- to two-day range.[1,2] Though we agree that transmission by fomites is unusual, we believe that it is prudent to recommend at least minimal laundering and/or changing of bedclothes and linen. Perhaps the high initial treatment failure rate (40%) reported by Burns et al was from reinfestation through contaminated fomites.

We support the authors' decision not to use lindane (gamma benzene hexachloride) on neonates. However, they also stated that they could find no data to support the assumption that there is an increased likelihood of toxicity in neonates. Ginsberg et al[3] showed a borderline correlation between increasing serum lindane levels and decreasing age. Animal studies have shown significant brain levels from absorption of topically applied lindane.[4] Reports have described seizures and other CNS symptoms after use of lindane in all age groups,[5] but predominately in infants.[6]

The authors stated that antibiotic therapy was unnecessary since all evidence of secondary infection in patients treated with antiscabietic therapy alone cleared within a few days. There was no indication that bacterial cultures were taken from any patient, except the single patient who did receive antibiotics for a presumed staphylococcal dermatitis [sic]. Glomerulonephritis secondary to nephritogenic streptococci complicating a scabietic infestation has been reported.[7] If systemic antibiotic therapy is to be withheld in clinical pyodermas, then cultures should be taken to exclude these organisms.

In Reply.—Drs Dolezal and Plamondon bring out several aspects of scabies that were mentioned only briefly in our publication due to the limited scope of the article. A unique feature of the current pandemic is that classic scabies is seldom seen and less typical varieties such as minimal scabies in the unsoiled patient are predominating.[1-3] Only 7% of more than 1,000 patients studied in Goa, India from 1969 to 1970 were found to have burrows.[4] In the study of Hejazi and Mehregan,[5] burrows were absent in over 70% of patients. No burrows were present in any of the neonates described in our study (nor in 11 additional neonates examined since). In only four of the contacts of these 16 infants was there even a suggestion of a burrow.

Whether one states that mite survival time is a few hours or one to two days is a matter of semantics rather than a difference of opinion. Under

ideal conditions, mite survival away from the human host has been observed for up to 96 hours.[6] (My own observations noted a disappointing seven hours in one case and 11 hours in a hardier female.)

The role of fomite transmission was clearly delineated by Mellanby's classic experiments with human volunteers.[7] After six months, he was able to transmit scabies via fomites in only two persons who exchanged underclothes directly with infected subjects. When underclothes were allowed to sit (unlaundered) for two or more days, no transmission occurred. Blankets, bedclothes, and outer garments were shown to have no role in transmission of the mite. In like manner, meticulous studies conducted during World War II by the Medical Research Council of the United Kingdom showed that it is exceedingly difficult to transmit scabies by any fomite.[8] Many physicians still insist on strict laundering and sterilization of fomites, but this simply is not necessary. At most, a simple change of clothing (specifically underclothes) after therapy is all that is needed.

I was pleased to note that Drs Dolezal and Plamondon supported our position against the use of lindane in very young children. Unfortunately, when our literature search on lindane was conducted, their references had not yet been published.

Cultures were taken from all of our infant patients. From two infants, coagulase-positive staphylococci were isolated, and *Staphylococcus epidermidis* was recovered from another. The relationship between acute glomerulonephritis (AGN) and nephritogenic group B streptococci is well documented. Though the relationship between AGN and scabies is less well defined, the potential is certainly there. We still, however, reserve the use of antibiotics for those cases where superinfection is severe and nephritogenic strains are isolated. The injudicious use of antibiotics in other patients is not warranted.

Psychological Factors in Diabetes Mellitus

In their extensive and excellent review in the JOURNAL on the psychological factors in diabetes mellitus (133:1061-1066, 1979), Greydanus and Hofmann missed three books and proceedings of recent meetings[1-3] devoted to the psychological aspects of diabetes in children, in which investigations from various professions from all over the world were brought together.

For the past 20 years we have been convinced that once diagnosed, diabetes becomes a somatopsychic disease in juveniles and a source of anxiety for the parents.[4] We have seen that without the achievement of emotional stability in the family, the diabetes in the child cannot be controlled.[5] Our experience has led us to include psychologists and social workers in the team treating diabetic children and adolescents.[6]

In Reply.—I thank Professor Laron for his interest and remarks. It was not possible to include all pertinent references and books in the compilation of our review. Thus, with some exception, attention was mainly directed to articles in peer-review journals. I welcome the inclusion of the cited symposiums.

I fully agree with his comments regarding the importance of family stability in the life of juvenile and adolescent diabetics. The review sought to present an overview of psychological or emotional factors in stabilizing teenage diabetics. As indicated, there are many factors involved, each one of which needs more investigation. Many approaches are used in seeking to prevent or manage "poor" teenage diabetic control. I emphasize a primary physician-adolescent patient relationship in which the clinician seeks to invest as much self-care as possible.[1] The family is encouraged to contribute to this therapeutic plan. Physician, adolescent, and parents form a team to aid with successful management. Psychiatric or psychological care is necessary if brittleness develops on an emotional basis.

The use of psychologists or social workers as part of a team dealing with the patient may be useful for many. The Adolescent Medical Clinic at the University of Rochester (NY) Medical Center emphasizes an approach utilizing a pediatric or adolescent medicine specialist to care for the diabetic patient, with psychiatric or psychological evaluation and consultation as needed. The family remains an important part of the health care plan. Some note that direct family therapy is important for labile diabetics.[2] I have found this useful in some but not all diabetics. It is up to the clinician to decide which therapeutic approach fits a particular teenage diabetic and his/her family. More research is needed in this area.

Filling a need since 1927

"In offering Similac to the Medical Profession we do so with the thought in mind that breast milk is nature's food for the infant, but as many infants are deprived of their natural food, either wholly or in part, some form of nourishment must be substituted, and Similac is offered as this substitute."

The above statement appeared in medical journals in the announcement of the introduction of Similac® Infant Formulas in 1927. Today, as then, we continue to recognize and support breast-feeding as the ideal feeding for infants.

Over the years, Ross Laboratories has promoted and supported breast-feeding by providing health professionals with service materials and patient counseling literature.

However, it should be recognized that not all infants will be breast-fed throughout the first year of life. Similac With Iron is offered for your consideration as a better alternative than cow milk if the mother discontinues breast-feeding early, if a supplement to breast-feeding is needed, or if breast-feeding is not adopted.

Our objective is to provide an appropriate infant feeding for those instances when an infant does not receive breast milk. We are proud of Similac Infant Formulas and are proud to have filled a need for high quality infant feeding for over 50 years.

Project Head Start: A Legacy of the War on Poverty, edited by Edward Zigler and Jeanette Valentine, 610 pp, $22.50, New York, Macmillan Publishing Co Inc, 1979.

In recent years, it has seemed that we Americans are so given to self-flagellation that we cannot stand up and applaud anything. There were some victories scored in Lyndon Johnson's war on poverty, but none greater than Project Head Start. As the book jacket states:

> When Project Head Start was organized in 1965, its goals mirrored the hopes of millions of impoverished Americans. Initially funded as a short-term effort, Head Start has become, after more than a decade of operation and a cost of approximately $2 billion, the most ambitious educational, social and health program for young children and their families in United States history.

This book, edited by Edward Zigler and Jeanette Valentine, examines the experience through the eyes of 35 authors from many disciplines. Most of them had a hand in Head Start.

As with most multiauthored volumes, there is much repetition. Tight editing is not in evidence. A few chapters were published previously and add to the bulk. Then there is too much "old-boy" reminiscing ("where I was when I got the call from Sarge Shriver") of interest only to the Head Start "in-group." With these few insignificant caveats, I recommend the book as required reading for anyone interested in early childhood evaluation.

My three favorite chapters are the ones by Catherine Ross on the historical roots of Head Start, by James Robinson and Willa Barrie Choper on parents' perspective of Head Start, and by Francis Palmer and Lucille Andersen reviewing the numerous longitudinal studies on long-term gains from early intervention. An interesting historical note is provided on the premature release of the so-called Westinghouse report in 1969, purporting to show the program's failure. Richard Orton says that the resultant publicity ("the blackest day in the history of the program") was directly orchestrated by the Nixon White House in an effort to kill Head Start. The blackest day as far as pediatricians are concerned is when the American Academy of Pediatrics lost the consultation contract to the self-same Westinghouse Corporation. This issue is politely glossed over in the book, with some pablum about "administrative difficulties" within the Academy. Another item not discussed is the virtual exclusion of handicapped children from Head Start.

What is continually stressed is that Head Start should not be viewed as simply an educational experience. I agree that "the innovative idea . . . is that effective intervention in the lives of children can only be accomplished through involving parents and the community in the intervention effort." In these days of militant teachers unions, and legal wrangles over busing, parents are less involved in their children's public school education.

For middle and upper class America, 4 years has become the accepted age to start school. Where does this leave the children of the poor who are most in need of an enriched environment? Head Start is the only hope and this book tells why.

ABRAHAM B. BERGMAN, MD
Children's Orthopedic Hospital
and Medical Center
4800 Sand Point Way NE
Seattle, WA 98105

Pediatric Nephrology, by Charles E. Hollerman, 501 pp, $16.50, Garden City, NY, Medical Examination Publishing Co Inc, 1979.

The intent of this book, as declared in the preface, is to provide information about the diagnosis and treatment of renal disease for physicians providing primary care to neonates, children, and adolescents. Accordingly, this text differs from those like *Pediatric Nephrology* by Rubin and Barratt, *Pediatric Kidney Disease* by Edelmann, or *Pediatric Nephrology* by Royer et al that are intended primarily for nephrologists. Dr Hollerman's text is akin to *Renal Disease in Childhood* by James, which is also intended for primary care physicians. It is also comparable to the James' text in that it is single authored and thus reflects opinions and experiences of a single physician.

The book is arranged in 16 chapters and covers the entire spectrum of renal disorders that affect neonates, children, and adolescents. It is a paperback book with offset printing that is convenient to carry and easy to read. Topics covered include glomerular and tubular disorders, genetic diseases, hypertension, renal disorders of the neonate, acute and chronic renal failure, and a chapter on dialysis and transplantation. All chapters contain current information and the list of references at the end of each chapter reflects careful selection of the best reviews and current papers on the subject of the chapter. At the end of each chapter is a series of five multiple-choice questions whose answers are given in a short essay.

As the author states, his opinions prevail throughout the text, which results in the shortcomings of this book. In a brief text like this there is little room for a discussion of the pathophysiology of glomerular or tubular disorders, and the pathophysiologic mechanisms of acute renal failure are discussed by merely listing the prevailing theories. The major arguments on either side of certain controversial topics are not covered, eg, the use of anticoagulant therapy of the hemolytic uremic syndrome, the use of corticosteroids for membranous nephropathy, high-dose intravenous methylprednisolone treatment of rapidly progressive glomerulonephritis or other crescentric glomerulonephritides. Some nephrologist might not dismiss the value of a low-salt diet in edematous nephrotic children or might believe that a 30-hour water deprivation test is needed to evaluate maximal urinary concentration capacity. In the discussion of antihypertensive agents, neither saralasin or captopril, which act to block the renin-angiotensin system, are discussed. This would be helpful since these agents act by an entirely separate mechanism than those listed. There is no discussion of plasmapheresis as a mode of treatment of glomerulonephritis or of lactic dehydrogenase isozyme pattern for detecting the location of urinary tract infections. Some obscure topics are covered, such as amyloidosis associated with familial Mediterranean fever and Ehlers-Danlos syndrome, and yet there is no

indication that the former can be treated with colchicine or that the latter is associated with renal tubular acidosis. Perhaps the most confusing aspect was the inclusion of the site of action and dosage of various diuretics in a chapter on the assessment of renal symptoms.

Despite these minor shortcomings, this is an excellent text. The references are particularly useful and I plan to use them extensively over the next few years as they are both comprehensive and current. Each chapter contains some very good tables that in many instances have been compiled by the author from several sources in order to construct tables of real use to the clinician. The table on renal growth during childhood is most impressive. There are clear descriptions of all disease entities and the chapter on renal dysplasia, hypoplasia, and cystic disease is very clear. The index is complete.

The relatively low price of this book and its clear, concise presentation make it a valuable text for primary physicians and residents treating children with renal disorders. I intend to recommend it to our residents.

RUSSELL CHESNEY, MD

Textbook of Child Neurology, ed 2, by John H. Menkes, 695 pp, Philadelphia, Lea & Febiger, 1980.

The second edition of Menkes' *Textbook of Child Neurology* remains the most generally useful in the field. It is comprehensive, yet not oversized, the second edition representing the addition of about 100 pages. Menkes cites a number of developments, particularly the computerized tomographic (CT) scan, to warrant the second edition, but in fact CT scan representation of neurologic disease is not extensively presented. For example, the section on "Congenital Anomalies" would profit by more in vivo CT illustrations of the gross malformations described, and a number of other sections would profit as well. The book retains the considerable advantage of essentially single authorship, which gives balance and not too much bias to the presentation. At the same time, the contribution by colleagues is excellent, particularly Dr Gabriel's discussion of malformations of the CNS and Dr Kinsbourne's chapter on "Disorders of Mental Development." As might be expected, the section on metabolic disease is strong, as is the chapter on "Paroxysmal Disorders," both areas of particular interest of the author, especially metabolic disease where Dr Menkes has made substantial contributions and displays a strong grasp of the biochemical aspects. One wonders, however, why metachromatic leukodystrophy and Krabbe's disease still find their home in the chapter on heredodegenerative disorders rather than in the more appropriate section on metabolic disease, inasmuch as the basic defects are as well understood as most disorders contained in the metabolic chapter. I also wonder why he retains the chapter heading "Perinatal Trauma" when the subject covered, and certainly the problem in 1980, is better described as "hazards of birth in the perinatal period." Also, a somewhat more extended and in-depth presentation of the modern issues related to intraventricular hemorrhage in the premature would be useful.

However, the real judgment on this book is not based on a number of small points but is to state again unequivocally that this is the most comprehensive yet concise presentation of child neurology for a readership that includes pediatricians, generalists, and people who are in training for pediatrics, neurology, or child neurology. It is an excellent book, better than the first edition in a number of ways, and will surely warrant a third edition in a few years.

CHARLES F. BARLOW, MD
Children's Hospital Medical Center
300 Longwood Ave
Boston, MA 02115

Muscle Disorders in Childhood, by Victor Dubowitz, 282 pp, Philadelphia, WB Saunders Co, 1978.

This monograph is 16th in the series *Major Problems in Clinical Pediatrics.* It lives up to the excellent reputation of the series by presenting the personal approach to muscle disorders of Victor Dubowitz, MD, who is internationally known and respected for his expertise in this area. The presentation is systematic, well written, and profusely illustrated, as well as authoritative. The confusing nomenclature of the ultrastructurally designated congenital myopathies is well handled, though one comes away with the notion that separation of this group of nonprogressive or very slowly progressive disorders is artificial at this level, and perhaps a fresh start with less emphasis on ultrastructure is the way of the future.

In addition to a workman-like presentation of the expected subjects of dystrophy, disorder of the lower motor neurons, myasthenia gravis, and the inflammatory myopathies, the author deals effectively with the somewhat newer and therapeutically important issues, such as carnitine myopathy and malignant hyperpyrexia. The expected chapter on the "floppy infant syndrome" is well covered, as is the section that deals with arthrogryposis and congenital contractures, which correctly presents this latter group as a symptomatic expression of prenatal neurologic disorder of movement in utero. With regard to the floppy infant, I suspect that the disappearance of this favorite subject of pediatric neurologists will coincide with a true coming of age of the field, vis-à-vis adult neurology. The adult neurologists have gone several generations beyond the floppy adult, but they still have their "stiff man." Probably the weakest chapter in the book is the one that deals with disorders of movement.

All in all, it is an excellent presentation of an important aspect of pediatrics and can be fully recommended as authoritative and up to date.

CHARLES F. BARLOW, MD
Boston Children's Hospital
300 Longwood Ave
Boston, MA 02115

Emergency Radiology of the Acutely Ill or Injured Child, by Leonard E. Swischuk, 496 pp, with illus, $45, Baltimore, Williams & Wilkins Co, 1979.

This book of almost 500 pages is devoted to that aspect of emergency pediatrics for which diagnoses are made with the aid of radiological examinations. The author aims to outline (1) general approaches to diagnostic problems, (2) helpful rules of thumb, and (3) specific diagnostic signs. Sometimes he delves convincingly into pathophysiologic-roentgenographic correlations.

The roentgenographic contribution is emphasized with 564 figures of generally excellent quality, which contain approximately 1,088 roentgenograms. Only a few examples of other radiological diagnostic methods are included: nine computerized tomograms, three sonograms, and five radionuclide scans. Illustrative line drawings are effectively used in 25 instances to

help clarify diagnostic features. One graph and three tables also complement the text. Pertinent, recent, and mainly US references are conveniently listed after each subsection, which allows for easier retrieval.

Normal variations, where appropriate, are distinguished from abnormal findings, especially in the skull, vertebral column, and limbs.

A few controversial concepts, such as those concerning intussusception and methods of reduction are offered, but mainly a conventional viewpoint is espoused.

The book is not comprehensive, and the statement "... a complete discussion is beyond the scope of this book..." is appropriately used in several instances.

Overall, the aims of the author are more than adequately accomplished, and the book is a useful addition to the radiology literature of pediatrics. It contributes substantial information on the radiologic aspects of the acutely ill or injured child. It should benefit pediatricians, general radiologists, residents, and medical students.

125 DeSoto St
Pittsburgh, PA 15213

Fetal and Maternal Medicine, by E. J. Quilligan and Norman Kretchmer, 681 pp, $40, Somerset, NJ, John Wiley & Sons Inc, 1980.

The true scope of perinatal medicine, the study of human creation, is vast. No one book can encompass the psychological, physiological, and pathophysiological processes involved from conception through a successful neonatal period, but Drs Quilligan and Kretchmer have done for perinatal medicine what Mahler and Handel did for a different Creation: captured its spirit. They did not attempt to write a bible.

In *Fetal and Maternal Medicine*, Drs Quilligan and Kretchmer have gathered together edited contributions from noted authorities and produced a valuable resource book for nurses and physicians interested in perinatal medicine. The content of the book is divided into three sections: basic concepts, systemic problems, and specific diseases. The assignments are sometimes quite arbitrary: for example, the inclusion of "Pulmonary Surfactant and the Respiratory Distress Syndrome" under basic concepts. Nevertheless, the editors were able to maintain a clear focus on the mother, her problems as they affect her and the fetus, and the period immediately after birth. The initial chapter on statistics on perinatal morbidity and mortality lays a solid foundation for consideration of the subsequent subjects. A few of the chapters are somewhat skimpy ("The Effects of Drugs on Uterine Contractility," "Fetal Distress"); most are very good; and a few ("Human Perinatal Endocrinology," "Immunology") are outstanding summaries of complex areas. The only chapter that seems out of place in this constellation is the final one, which considers the low birth weight infant and its bilirubin problems. In general, the writing is clear and concise, and material is presented in a well-organized and easily readable format. Although perhaps not covered systematically, almost all important subjects relevant to maternal-fetal medicine are covered. One notable exception is the role of intrauterine physical environment on dysmorphogenesis.

In the introduction, the editors stated their desire to have each subject discussed jointly by a pediatrician and an obstetrician. Although only three of the 27 chapters are the product of such a collaboration, the partnership of a pediatrician and an obstetrician in editing the book is reflected throughout and is symbolic of today's partnership in perinatal medicine. This book would serve equally well as a reference source for pediatricians or obstetricians, a high compliment for books in this area. I commend the editors and recommend their book to professionals in need of an up-to-date, reasonably comprehensive, lively resource work in perinatal medicine.

DONALD SHAPIRO, MD
Strong Memorial Medical Center
University of Rochester
Rochester, NY 14642

Adolescent Medicine in Primary Care, by Walter R. Anyan, Jr, 387 pp, New York, John Wiley & Sons Inc, 1978.

Dr Anyan wrote this book primarily for health care practitioners whose disciplines are pediatrics, internal medicine, and family medicine. The intent of the book is to focus on specific aspects of adolescent health care, development processes, and disorders that are specific to the adolescent. It is not intended to be an encyclopedia for all medical disorders that occur in the adolescent but rather those that are most peculiar to or influenced by the process of adolescence.

The book is divided into three general sections. The first is on organization and conduct of adolescent primary care. This general approach to history taking, physical examination, and the data base is a more than adequate guide to the different approaches to and the different needs of the adolescent, as differentiated from the child or adult.

The second section focuses on the physiologic basis for adolescent care, specifically sexual maturation and the pubertal process. This section is relatively long and in some parts it is more detailed than is necessary for clinical care of the adolescent. Specifically, the section on "Changes in Hypothalamic and Anterior Pituitary Function" is much too complex for the physician involved in giving clinical care to the teenager. The same holds true for the discussion on changes in body composition. Though the concepts are important, the detailed presentation is probably not necessary for the intended audience of this book.

In the third section, the choice of topics for clinical problems in adolescence is appropriate though limited. For example, the major clinical conditions associated with the sexually active adolescent are adequately explored. Exceptions are the difficult problems associated with the diagnosis and treatment of pelvic inflammatory disease, which were not adequately emphasized. In addition, the section on teenage pregnancy does not reflect the major issues associated with this difficult problem nor the kinds of approaches necessary to try to resolve it, either on an individual basis or as a national problem.

The major difficulty with this book is the unevenness of the treatment of subjects throughout. That is, some subjects are discussed in a much too detailed fashion, while others are treated too superficially. Generally, the writing is literate and the book is easy to read. This book would be valuable for house staff and practicing physicians in pediatrics, internal medicine, and family practice.

FELIX P. HEALD, MD

Baltimore, MD 21201

HOW TO FI

A FOUR-STEP BLUEPRINT

STEP 1.

INVITE 150 PRACTICING PHYSICIANS TO TALK ABOUT PEDIATRIC COUGH/COLD LIQUIDS.

THEN, LISTEN TO THEIR COMPLAINTS.

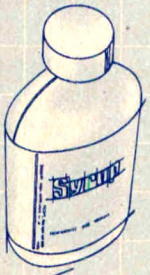
Sometimes a revolution begins by simply taking the obvious first step. Bristol Laboratories conducted a series of interviews and panel discussions with 150 physicians having active pediatric practices in all parts of the country.

Here are some of the comments heard most frequently:

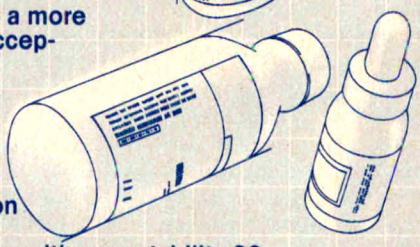
"...they've had too many mixtures. If you want an antihistamine, you should prescribe the antihistamine plain."

"I've decided that, given a choice, I would never go with a narcotic formula."

"[A dosage schedule]...is really probably better by weight than by age. And it's helpful to have both."



"If you can, make a more concentrated, acceptable solution... higher doses of drug are more effective."



"...expectoration and decongestion are my prime objectives—along with acceptability."

"Pseudoephedrine is a stimulant. I don't think it's a good idea in infants under two years."

"[When treating very young children,] you don't want to suppress the cough."

"I do not prescribe codeine for small children. I prefer dextromethorphan."

"I think the taste factor is also important...so do the mothers!"

BRISTOL™

©1980 BRISTOL LABORATORIES
Division of Bristol-Myers Company
Syracuse, New York 13201

STEP 2.

RECOGNIZE THAT WHAT *ISN'T* PU PEDIATRIC COUGH/COLD LIQUID IS JUST AS IMPORTANT AS WHA

Depending on patient age, these component regarded as undesirable by most of the phy consulted:

FOR INFANTS
No cough suppressant to interfere with expectoration of mucus.

FOR INFANTS & CHILDREN
No antihistamine to produce excessive drying side effects. Antihistamines are counterproductive to the mucous-liquifying action of expectorants.

FOR INFANTS & CHILDREN
No pseudoephedrine, with its assc higher incidence of CNS side effect

FOR INFANTS & CHILDI
No codeine or other narcotic atives.

FOR INFANTS & CHILDREN
No subtherapeutic formulations, treatment failure or necessitating inc dosage.

INTRODUCIN

IDS' COUGHS.

TIONAL SYMPTOMATIC THERAPY.

STEP 3. STEP 4.

DESIGN A SIMPLE, HIGH-POTENCY FANT COUGH/COLD FORMULA.

BEFORE PROCEEDING, REVIEW STEP 1.)

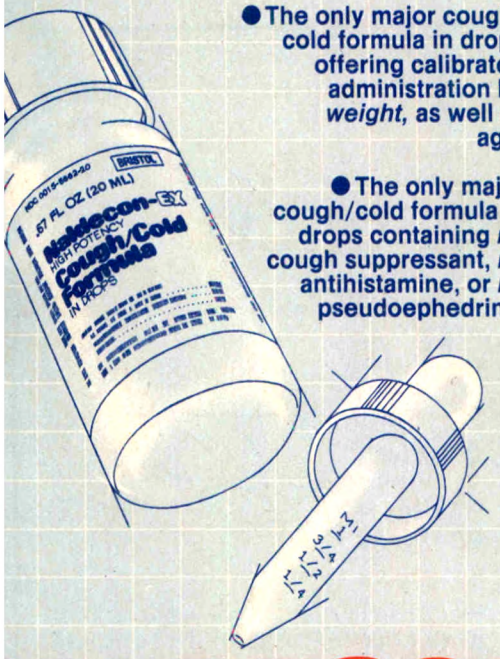
1 ml dropperful contains:

ylpropanolamine HCl . . . . . 9 mg
fenesin (glyceryl guaiacolate) . . . . . 30 mg
hol 0.6%

symptomatic relief of coughing and nasal bronchial congestion due to colds, flu, bron- s and croup.

nly major cough/cold formula in drops based mg of expectorant action (guaifenesin) to en- e productive coughing.

nly major cough/cold formula in drops includ- enylpropanolamine, a decongestant with mini- S side effects.



- The only major cough/cold formula in drops offering calibrated administration by *weight*, as well as age.
- The only major cough/cold formula in drops containing *no* cough suppressant, *no* antihistamine, or *no* pseudoephedrine!

NEXT, DEVELOP A HIGH-POTENCY COUGH/COLD PRODUCT FOR AGES 2 TO 12.

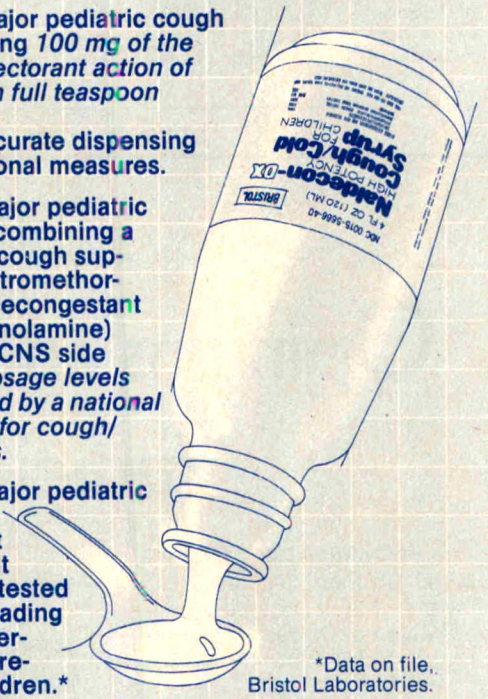
(REFER TO SPECIFICATIONS IN STEP 1.)

Each teaspoonful (5 ml) contains:

Phenylpropanolamine HCl . . . . . 9 mg
Dextromethorphan hydrobromide . . . . . 7.5 mg
Guaifenesin (glyceryl guaiacolate) . . . . . 100 mg
Alcohol 5%

For symptomatic relief of coughing and nasal and bronchial congestion due to colds or flu.

- The only major pediatric cough syrup delivering *100 mg of the powerful expectorant action of guaifenesin in full teaspoon doses.* —insuring accurate dispensing without fractional measures.
- The only major pediatric cough syrup combining a non-narcotic cough suppressant (dextromethorphan) and a decongestant (phenylpropanolamine) with minimal CNS side effects—*at dosage levels recommended by a national review panel for cough/cold products.*
- The only major pediatric cough syrup with the great Naldecon fruit flavor—taste-tested against the leading brand and overwhelmingly preferred by children.*



*Data on file, Bristol Laboratories.

- And, Naldecon-DX contains *no* codeine and *no* antihistamine!

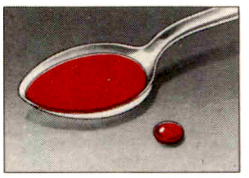
"All clear for landing..."

Head's all clear, too!

Sudafed®



(pseudoephedrine HCl) 30 mg tablets/syrup

Opens the nose without closing the eyes

Don't let nasal/sinus congestion ground young pilots...relieve their symptoms with raspberry-flavored SUDAFED syrup or tablets.

Single-entity SUDAFED keeps young patients alert and on the go. It won't interrupt or interfere with their daily activities.

No alcohol. No aspirin. No antihistamines.

Just safe and effective decongestant action.

Be a hero to your young patients. Unclog their stuffed heads with SUDAFED.

Recommend Sudafed... For decongestion without drowsiness

ONE HUNDRED YEARS WELLCOME

Burroughs Wellcome Co.
Research Triangle Park
North Carolina 27709

Just a touch can transfer impetigo.

And just a touch of the right antibiotic can help clear it up.

Neosporin Ointment can help control minor cases of impetigo before other children catch it from your young patient, and it may be used as an adjunct to appropriate systemic therapy in more extensive disease. Neosporin Ointment provides broad, reliable antibiotic action against susceptible organisms—notably *Staphylococcus* and *Streptococcus*— with antibiotics that are seldom used systemically.

Neosporin® Ointment

(polymyxin B—bacitracin—neomycin)

Each gram contains: Aerosporin® brand Polymyxin B Sulfate 5,000 units; zinc bacitracin 400 units; neomycin sulfate 5 mg (equivalent to 3.5 mg neomycin base); special white petrolatum qs. In tubes of 1 oz and 1/2 oz and 1/32 oz (approx.) foil packets.

Warning: Because of the potential hazard of nephrotoxicity and ototoxicity due to neomycin, care should be exercised when using this product in treating extensive burns, trophic ulceration and other extensive conditions where absorption of neomycin is possible. In burns where more than 20 percent of the body surface is affected, especially if the patient has impaired renal function or is receiving other aminoglycoside antibiotics concurrently, not more than one application a day is recommended.

When using neomycin-containing products to control secondary infection in the chronic dermatoses, it should be borne in mind that the skin is more liable to become sensitized to many substances, including neomycin. The manifestation of sensitization to neomycin is usually a low grade reddening with swelling, dry scaling and itching; it may be manifest simply as failure to heal. During long-term use of neomycin-containing products, periodic examination for such signs is advisable and the patient should be told to discontinue the product if they are observed. These symptoms regress quickly on withdrawing the medication. Neomycin-containing applications should be avoided for that patient thereafter.

Precautions: As with other antibacterial preparations, prolonged use may result in overgrowth of nonsusceptible organisms, including fungi. Appropriate measures should be taken if this occurs.

Adverse Reactions: Neomycin is a not uncommon cutaneous sensitizer. Articles in the current literature indicate an increase in the prevalence of persons allergic to neomycin. Ototoxicity and nephrotoxicity have been reported (see Warning section).

PAIN GONE

while the antibiotic gets going

An effective adjuvant to systemic antibiotic treatment, AURALGAN promptly relieves the pain and reduces the inflammation of acute otitis media, while the antibiotic of choice fights the infection.

AURALGAN contains the topical analgesic action of benzocaine and antipyrine plus glycerin dehydrated...a decongestant so hygroscopic that it "blots up" excess moisture through the tympanic membrane, for relief of pressure and pain in the middle ear.

BRIEF SUMMARY
(For full prescribing information, see package circular.)
AURALGAN® Otic Solution
Each ml contains:

Antipyrine	54.0 mg
Benzocaine	14.0 mg
Glycerin dehydrated q.s. to	1.0 ml

(contains not more than 1.0% moisture) (also contains oxyquinoline sulfate)

INDICATIONS: *Acute otitis media of various etiologies*
—prompt relief of pain and reduction of inflammation in the congestive and serous stages
—adjuvant therapy during systemic antibiotic administration for resolution of the infection

CONTRAINDICATIONS: Hypersensitivity to any of the components or substances related to them./In the presence of spontaneous perforation or discharge.

DOSAGE AND ADMINISTRATION: *Acute otitis media:* Instill AURALGAN, permitting the solution to run along the wall of the canal until it is filled. Avoid touching the ear with dropper. Then moisten a cotton pledget with AURALGAN and insert into meatus. Repeat every one to two hours until pain and congestion are relieved.

HOW SUPPLIED: No.1000—AURALGAN® Otic Solution, in package containing 15 ml (½ fl oz) bottle with separate dropper-screw cap attachment.

...in acute otitis media

Auralgan®

OTIC SOLUTION

FULLY COMPATIBLE WITH SYSTEMIC ANTIBACTERIAL THERAPY. ON PRESCRIPTION ONLY.

Why upset a feverish child's stomach with aspirin?

A child's complaints of nausea and stomachache may be a consequence of aspirin therapy. It has been clinically documented that therapeutic doses of aspirin may cause G.I. problems ranging from minor upset[1-3] to serious, but less frequent, ulceration and gastric hemorrhage.[4,5]

Why complicate fever therapy with gastric problems? With Children's TYLENOL you can effectively reduce his fever with virtually no G.I. risk.[6,7]

Advertising Principles: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request.

Subscription Rates: The yearly rates for the AMERICAN JOURNAL OF DISEASES OF CHILDREN is as follows: for members of the AMA, $1.50, included in the annual membership dues; for nonmembers, $24 for one year, $40 for two years in the United States and US possessions; all other countries, $34 for one year, $60 for two years. Special yearly price to residents, interns, and medical students in the United States and US possessions, one year, $12; two years, $20. Address all subscription communications to Circulation-Fulfillment Department. Phone: 312, 751-6079.

Change of Address: POSTMASTER, send address changes to Helen R. Mazur, Director, Circulation-Fulfillment. Notification of address changes should be sent at least six weeks in advance, including both old and new address, and a mailing label taken from the most recent copy. Include your new zip code number.

AMERICAN JOURNAL OF DISEASES OF CHILDREN (ISSN 0002-922X) is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago and at additional mailing office.

ACTIFED-C® Expectorant Ⓒ

Each 5 cc teaspoonful contains: codeine phosphate 10 mg (Warning—may be habit-forming); Actidil® brand triprolidine HCl 2 mg; Sudafed® brand pseudoephedrine HCl 30 mg; guaifenesin 100 mg. Preservatives are methylparaben 0.1% and sodium benzoate 0.1%.

With the cough-stopping power of codeine.

Controls Excessive Coughing Without Preventing Productive Expectoration

Persistent, repetitive, dry coughs can be a problem in the pediatric patient, particularly at night when it often disturbs sleep. Actifed-C is made for this type of cough.

It contains codeine to reduce severity and persistence plus guaifenesin to liquefy and ease the expulsion of mucus. Moreover, Actifed-C is the only cough medication that contains triprolidine and pseudoephedrine... the decongestant/antihistamine combination that has been part of the NASA Space Medicine Kit since 1968.

Indications: Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Lacking substantial evidence of effectiveness as a fixed combination": For the symptomatic relief of cough in conditions such as: the common cold, acute bronchitis, allergic asthma, bronchiolitis, croup, emphysema, tracheobronchitis.

Final classification of the less-than-effective indications requires further investigation.

Warning: Use in Pregnancy: Experience with this drug in pregnant women is inadequate to determine whether there exists a potential for harm to the developing fetus.

Precautions: Although pseudoephedrine hydrochloride causes virtually no pressor effect in normotensive patients, it should be used with caution in patients with hypertension. In addition, even though triprolidine hydrochloride produces only a low incidence of drowsiness, appropriate precautions should be observed.

Side Effects: The great majority of patients will not have any side effects. Only certain patients, sensitive to one or another of the ingredients, may note mild stimulation or mild sedation.

Supplied: Bottles of 1 pint. Complete literature available on request from Professional Services Dept. PML.

Not recommended for use in children under 2 years of age.

ONE HUNDRED YEARS WELLCOME

North Carolina 27709

Instructions for Authors

General Information.—Send manuscripts by first-class (**not** registered) mail to the Chief Editor, Gilbert B. Forbes, MD, Box 777, 601 Elmwood Ave, Rochester, NY 14642. Designate one author as correspondent and provide his/her address and telephone number. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the *American Journal of Diseases of Children* and may not be published elsewhere without permission from the publisher (AMA).

In view of the provisions of *The Copyright Revision Act of 1976*, effective Jan 1, 1978, the author(s) of manuscripts, letters to the editor, and book reviews accepted for publication in the JOURNAL will be required to sign and date the following statement: "In consideration of the AMA taking action in reviewing and editing my/our submission, the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the AMA in the event that such work is published by the AMA."

Manuscript Preparation.—All the elements of a manuscript must be submitted in **triplicate, double-spaced throughout**. Use heavy-duty white bond paper, 21.6 × 27.9 cm, and 2.5-cm margins. If a word processor is used, do not justify lines. The style of writing should conform to proper English usage and syntax. All measurements are to be in metric units, temperatures in Centigrade.

All accepted manuscripts are subject to copy editing. The corresponding author will receive an edited typescript and layout for approval. Forms for ordering reprints are included with the edited typescript. Proofs will be sent for approval if requested by the author and if printing deadlines permit. The author is responsible for all statements in his/her work, including changes made by the copy editor.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines. The title page should include the full names and academic affiliations of all authors, the address to which requests for reprints should be sent, and, if the manuscript was presented at a meeting, the name of the organization, place, and date on which it was read.

Abstract.—Provide an abstract (135-word maximum) of the article, including statement of the problem, method of study, results, and conclusions. The abstract replaces the summary.

Informed Consent.—Manuscripts reporting the results of experimental investigations on humans must include a statement to the effect that informed consent was obtained from the parents or guardians after the nature of the procedure(s) had been fully explained.

Clinical Memoranda.—Brief accounts of interesting observations and clinical situations. Limited to 800 words plus one table or illustration; abstract unnecessary. Submit in triplicate, double-spaced. Copyright assignment required.

Letters to the Editor.—Correspondence pertaining to material published in the JOURNAL. Limit 500 words. Submit in triplicate, double-spaced, and clearly marked "For publication." Copyright assignment required.

References.—List in order of their appearance in the text, and type double-spaced, in the following manner:

1. Applebaum MM, Thaler MM: Reye syndrome without initial hepatic involvement. *Am J Dis Child* 1977;131:295-296.

Do not include unpublished data, personal communications, or manuscripts "in preparation" or "submitted" in the list of references. Such material, if essential, may be incorporated in the body of the article.

Illustrations.—Submit only high-contrast glossy prints in triplicate, unmounted and untrimmed. Preferred size is 12.7 × 17.3 cm (5 × 7 in). Figure number, name of first author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. Lettering must be legible after reduction to column size. Magnification and stain should be provided for histologic sections.

For illustrations in full color submit 35-mm, positive color transparencies, mounted in cardboard and carefully packaged. Do not submit glass-mounted transparencies; do not submit color prints. The fee is $275 for up to six square-finished color illustrations that can be arranged on one page. A letter of intent to pay the fee must accompany submission.

Legends.—Legends for illustrations should be typed double-spaced, beginning on a separate sheet of paper (40-word maximum for each).

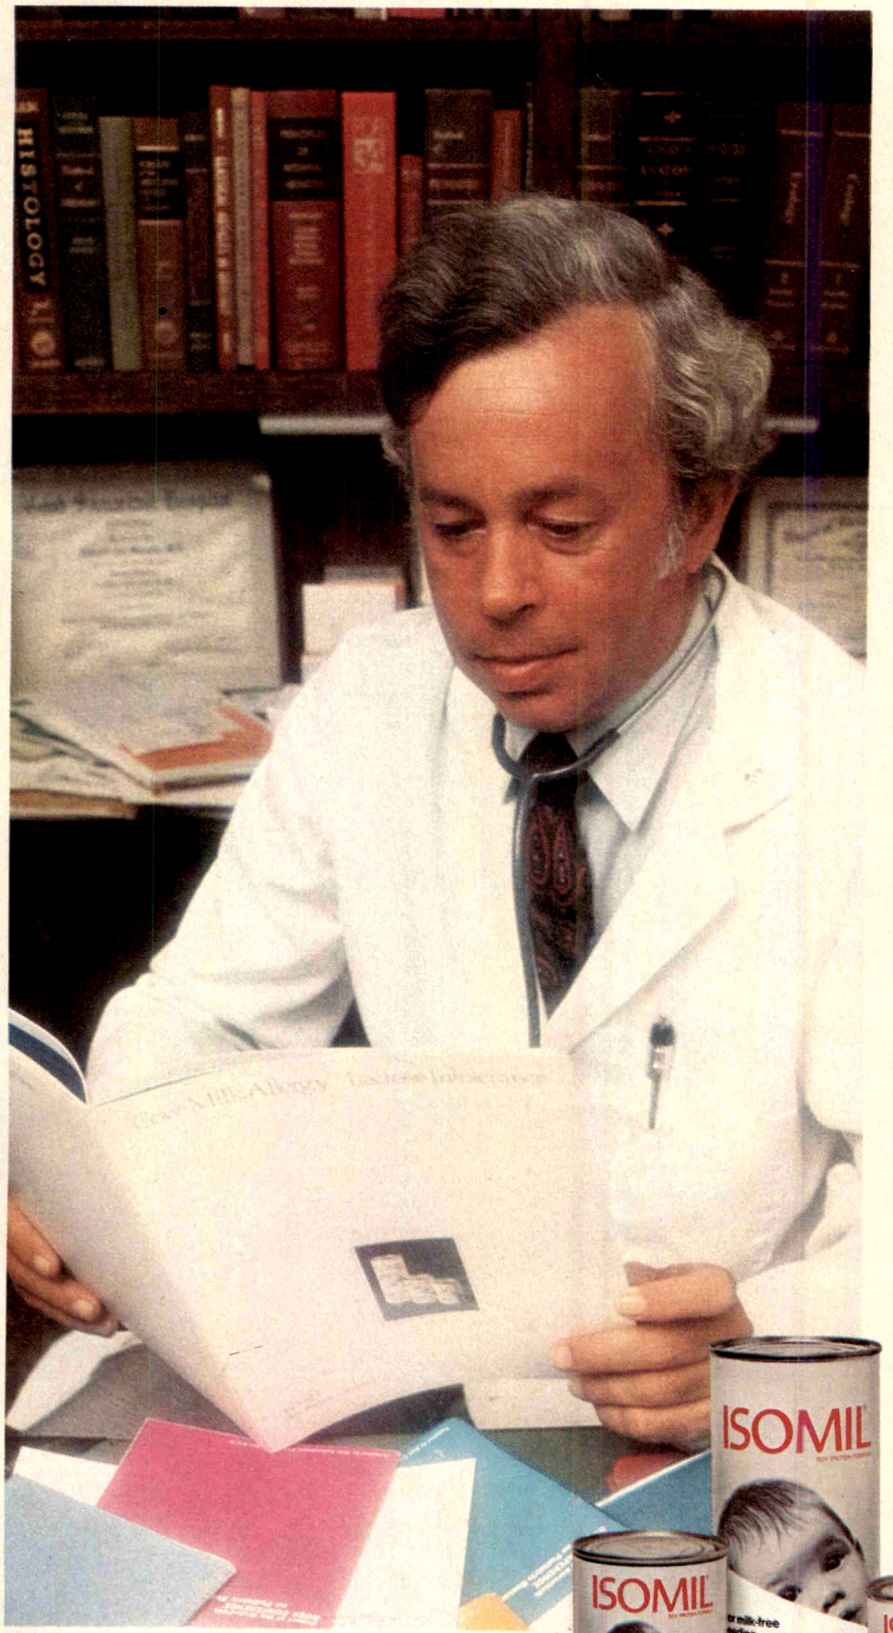
Acknowledgments.—Illustrations and tables from other publications must be suitably acknowledged, and accompanied by written permission from publisher and author.

Photographic Consents.—A signed statement of consent from **both** parents (or guardian) or the persons involved must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 21.6 × 27.9 cm paper. If a table must be continued, use a second sheet and repeat all heads. Each table must have a title.

Uniform Requirements.—Further details on manuscript preparation are given in the document *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* prepared by the International Steering Committee of Medical Editors. Reprints of this document are available by directing requests to this journal: Scientific Publications, 535 N Dearborn St, Chicago, IL 60610.

Clinical research is our tradition



What does a tradition of clinical research mean to you? Simply, it means you can recommend Isomil® Soy Protein Formula with confidence that your patients' nutritional needs will be met. One study, for example, documented that infants will grow as rapidly when fed Isomil as those infants fed a cow milk formula.[1] A second study confirmed these findings.[2]

Isomil was also found effective in preventing recurrence of diarrhea due to secondary lactose intolerance. One clinical study found that diarrhea recurrence rates were lower with the group fed Isomil than those fed a milk-based formula.[3] Another study confirmed these findings.[4]

These are four of the studies that have been conducted with Isomil. Clinical research is one reason you can recommend Isomil with confidence: for the infant with a sensitivity to cow milk or with secondary lactose intolerance.

HOW TO FIX

A FOUR-STEP BLUEPRINT T

STEP 1.

INVITE 150 PRACTICING PHYSICIANS TO TALK ABOUT PEDIATRIC COUGH/COLD LIQUIDS.

THEN, LISTEN TO THEIR COMPLAINTS.

Sometimes a revolution begins by simply taking the obvious first step. Bristol Laboratories conducted a series of interviews and panel discussions with 150 physicians having active pediatric practices in all parts of the country.

Here are some of the comments heard most frequently:

"...they've had too many mixtures. If you want an antihistamine, you should prescribe the antihistamine plain."

"I've decided that, given a choice, I would never go with a narcotic formula."

"[A dosage schedule]...is really probably better by weight than by age. And it's helpful to have both."

"If you can, make a more concentrated, acceptable solution... higher doses of drug are more effective."

"...expectoration and decongestion are my prime objectives—along with acceptability."

"Pseudoephedrine is a stimulant. I don't think it's a good idea in infants under two years."

"[When treating very young children,] you don't want to suppress the cough."

"I do not prescribe codeine for small children. I prefer dextromethorphan."

"I think the taste factor is also important...so do the mothers!"

Division of Bristol-Myers Company
Syracuse, New York 13201

STEP 2.

RECOGNIZE THAT WHAT *ISN'T* PUT PEDIATRIC COUGH/COLD LIQUIDS IS JUST AS IMPORTANT AS WHAT

Depending on patient age, these components v regarded as undesirable by most of the physic consulted:

FOR INFANTS
No cough suppressant to interfere with expectoration of mucus.

FOR INFANTS & CHILDREN
No antihistamine to produce excessive drying side effects. Antihistamines are counterproductive to the mucous-liquifying action of expectorants.

FOR INFANTS & CHILDREN
No pseudoephedrine, with its assoc higher incidence of CNS side effects.

FOR INFANTS & CHILDRE
No codeine or other narcotic d atives.

FOR INFANTS & CHILDREN
No subtherapeutic formulations, ris treatment failure or necessitating incre dosage.

INTRODUCIN

KIDS' COUGHS.
ATIONAL SYMPTOMATIC THERAPY.

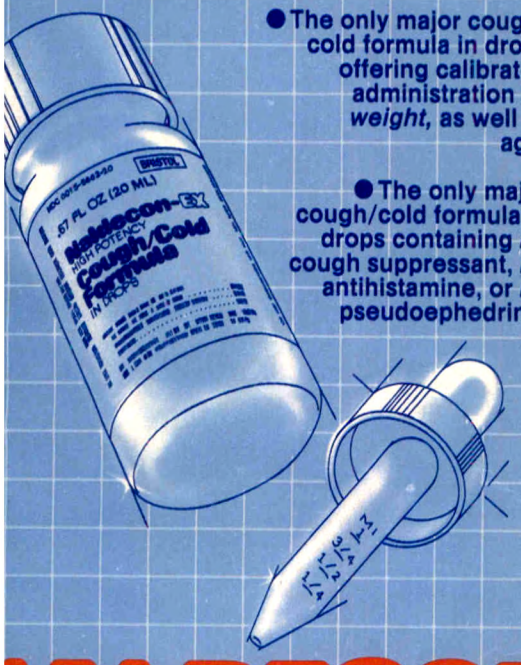
STEP 3.

W, DESIGN A SIMPLE, HIGH-POTENCY INFANT COUGH/COLD FORMULA.
(BEFORE PROCEEDING, REVIEW STEP 1.)

ch 1 ml dropperful contains:
henylpropanolamine HCl . . . . . 9 mg
uaifenesin (glyceryl guaiacolate) . . . . . 30 mg
cohol 0.6%
r symptomatic relief of coughing and nasal d bronchial congestion due to colds, flu, bron- itis and croup.

e only major cough/cold formula in drops based 0 mg of expectorant action (guaifenesin) to en- age productive coughing.

e only major cough/cold formula in drops includ- henylpropanolamine, a decongestant with mini- CNS side effects.



- The only major cough/cold formula in drops offering calibrated administration by *weight*, as well as age.
- The only major cough/cold formula in drops containing *no* cough suppressant, *no* antihistamine, or *no* pseudoephedrine!

STEP 4.

NEXT, DEVELOP A HIGH-POTENCY COUGH/COLD PRODUCT FOR AGES 2 TO 12.
(REFER TO SPECIFICATIONS IN STEP 1.)

Each teaspoonful (5 ml) contains:
Phenylpropanolamine HCl . . . . . 9 mg
Dextromethorphan hydrobromide . . . . . 7.5 mg
Guaifenesin (glyceryl guaiacolate) . . . . . 100 mg
Alcohol 5%
For symptomatic relief of coughing and nasal and bronchial congestion due to colds or flu.

- The only major pediatric cough syrup delivering *100 mg of the powerful expectorant action of guaifenesin in full teaspoon doses.* —insuring accurate dispensing without fractional measures.
- The only major pediatric cough syrup combining a non-narcotic cough suppressant (dextromethorphan) and a decongestant (phenylpropanolamine) with minimal CNS side effects—*at dosage levels recommended by a national review panel for cough/cold products.*
- The only major pediatric cough syrup with the great Naldecon fruit flavor—taste-tested against the leading brand and overwhelmingly preferred by children.*

*Data on file, Bristol Laboratories.

- And, Naldecon-DX contains *no* codeine and *no* antihistamine!

NALDECON-EX™ DROPS
NALDECON-DX™ SYRUP

THE PRACTITIONERS' COUGH FIXERS

Now, one System manages them all.

Only Mead Johnson provides the System of Hypoallergenic Formulas to manage feeding problems of infancy.

NUTRAMIGEN®
Hypoallergenic formula for infants and children with protein allergy.

ProSobee®
Milk-free, lactose-free, and now sucrose-free soy-based formula for common feeding problems.

PREGESTIMIL®
Hypoallergenic formula for infants and children with protein allergy complicated by malabsorption.

NUTRAMIGEN, PREGESTIMIL, and all Mead Johnson special formulas are made possible by your continued support of ENFAMIL® and PROSOBEE.
For more information on The System of Hypoallergenic Formulas, contact your Mead Johnson Nutritional Division Representative or write Mead Johnson Nutritional Division, Dept. 42, Evansville, IN 47721.

Evaluation of Neonatal Periventricular-Intraventricular Hemorrhage

A Major Advance

Periventricular-intraventricular hemorrhage is the most common and serious variety of neonatal intracranial hemorrhage.[1] The other major types of hemorrhage, ie, subdural hemorrhage, primary subarachnoid hemorrhage, and intracerebellar hemorrhage, are either very uncommon or not of major clinical importance. The enormous importance of periventricular-intraventricular hemorrhage is linked to the evolution of neonatal intensive care and, as a consequence, the dramatic improvements in survival rates for small premature infants. Because periventricular-intraventricular hemorrhage is characteristic of such infants, the occurrence of the lesion has reached nearly epidemic proportions in modern neonatal intensive care facilities.

The adaptation of the computerized tomographic (CT) scan to the evaluation of the small premature infant in the mid-1970s led to the recognition of the remarkably high incidence of the lesion. Thus, in two large studies in which small premature infants were subjected to CT scan routinely in the first week of life, the incidence of periventricular-intraventricular hemorrhage was found to be 40% to 45%.[2,3]

In the following discussion, a brief review of the neuropathology, pathogenesis, clinical features, evaluation, outcome, and management of neonatal periventricular-intraventricular hemorrhage will be presented. These issues are discussed in considerable detail elsewhere.[1] In this article, particular emphasis will be placed on the evaluation of periventricular-intraventricular hemorrhage and, particularly, the major advance in recognition of the lesion made possible by the use of real-time ultrasound scanning (see article by Allan et al p 1028 in this issue).

NEUROPATHOLOGY

The neuropathological appearance of periventricular-intraventricular hemorrhage is distinctive and dramatic. The essential lesion is a hemorrhage into the subependymal germinal matrix. This critical region, the source of cerebral glia in perinatal brain (and of neurons earlier in gestation), is richly vascularized. The hemorrhage emanates from capillaries within the matrix.[4]

The site of the hemorrhage within the matrix bears a distinct relation to gestational age.[5] In the majority of cases that are recognized during life, ie, infants of approximately 28 to 32 weeks' gestation, the lesion occurs principally at the level of the head of the caudate nucleus. In infants less than 28 weeks of gestation, the site of the lesion is usually over the body of the nucleus caudatus, and in mature infants, the choroid plexus.

Approximately 80% of the cases of matrix hemorrhage rupture into the ventricular system. Blood spreads through the ventricles into the basilar cisterns in the posterior fossa. An obliterative arachnoiditis results and causes the impairment in CSF flow that promotes hydrocephalus.

PATHOGENESIS

Major insight into the pathogenesis of periventricular-intraventricular hemorrhage has been gained in the past several years. Pathogenetic formulations should explain the strong association of the lesion with prematurity and with the hypoxic events so frequently observed in premature infants, as well as the characteristic periventricular locus of the lesion.

The association of the lesion with prematurity relates to four major factors. First, the subependymal germinal matrix, which provides poor support for the small vessels coursing through it, does not dissipate until term in the human brain. Second, a disproportionate amount of cerebral blood flow appears to be diverted to the periventricular region because of the particularly exuberant vascular supply to the matrix. Third, the integrity of the periventricular capillary bed appears to be tenuous. Fourth, vascular autoregulation, the process by which cerebral arterioles constrict or dilate to maintain constant cerebral blood flow despite changes in perfusion pressure, is impaired in the human newborn.[6]

The occurrence of the lesion in certain infants with serious hypoxic events, eg, asphyxia, relates to four major factors. First, vascular autoregulation is more severely impaired under such circumstances, thus exposing the periventricular capillary bed to bursts of pressure-flow that might cause rupture. Second, cerebral blood

flow initially is increased with events such as asphyxia. Third, venous pressure may be increased, secondary to myocardial failure. Fourth, a degree of injury to the metabolically active capillary endothelial cells may occur with hypoxic insults.

The characteristic periventricular locus of the lesion relates to five major factors. The first three, discussed above, have to do with the facts that the periventricular region is the site of the germinal matrix, of a relatively prominent arterial supply, and of a capillary bed with apparently tenuous integrity. In addition, certain anatomic peculiarities of the deep venous drainage in the periventricular region[7] and a relatively large amount of fibrinolytic activity in this region[8] also probably have pathogenetic importance.

CLINICAL FEATURES

The clinical features of this lesion can be categorized into two basic syndromes. The first is a catastrophic deterioration that usually occurs in infants with larger hemorrhages and results in a serious outcome. The second is a more saltatory or stuttering deterioration that usually occurs in infants with smaller hemorrhages and has a less serious outcome. The features of the second syndrome may be so subtle that they are readily overlooked. Indeed, in one careful study only approximately 50% of the cases of periventricular-intraventricular hemorrhage were correctly predicted to have the lesion on the basis of clinical criteria.[9]

EVALUATION

Recognition of neonatal periventricular-intraventricular hemorrhage requires three essential steps. The first is identification of the clinical setting (essentially every premature infant in a neonatal intensive care unit). The second is recognition of the characteristic CSF profile, ie, initially many RBCs and an elevated protein content, followed shortly by xanthochromia, and a depressed glucose content. In a study of 76 consecutive infants (< 2,000 g at birth) who had a CT scan following the finding of the characteristic CSF profile of intraventricular hemorrhage, we found that only six (8%) had a normal scan, 22 (29%) had primary subarachnoid hemorrhage only, and 48 (63%) had clearly discernible periventricular-intraventricular hemorrhage.[10] Thus, in the presence of a CSF profile that suggests hemorrhage, the third step in the diagnostic sequence, ie, imaging of the intracranial cavity by CT or sonar scan, is indicated.

A CT scan is a highly effective means of establishing the diagnosis of periventricular-intraventricular hemorrhage and of demonstrating the site and extent of the lesion. In addition, the size of the ventricles, pattern of ventricular dilation, and presence of major white matter lesions (eg, periventricular leukomalacia) may also be defined. Despite the value of the CT scan, it must be recognized that the procedure is not without hazard to the small premature infant. Maintenance of ventilation, circulation, and temperature are difficult problems during transport and during the procedure itself. Moreover, although with modern instruments the radiation dose to the brain and eyes is comparable with that of conventional skull roentgenograms, the long-term effects of multiple scans over short time periods remain unknown.

Ultrasonic scanning now appears to be a safe, effective alternative to the CT scan. Use of the real-time, mechanical sector scanner, placed over the anterior fontanel and oriented in the coronal plane, provides excellent resolution of periventricular as well as intraventricular hemorrhage. The extent of intraventricular blood and severity of ventricular dilation is demonstrated by use of the sector scanner oriented in the sagittal plane. Use of a linear-array transducer over the side of the cranium provides a horizontal projection (comparable to the usual CT scan), which is particularly useful to quantitate degree of ventricular dilation (though is less effective in our hands in resolution of periventricular-intraventricular hemorrhage).

The ultrasonic technique is particularly attractive because portable instruments can be used; thus, the infant need not be transported or otherwise disturbed. Several studies can be performed over relatively short time periods, presumably without harm from the pulsed ultrasound. Such studies have obvious and major value for management, and may prove enormously useful for delineation of the pathogenesis of the hemorrhage. It is in the latter area that ultrasound may provide its greatest contribution, because the major goal of the management of periventricular-intraventricular hemorrhage is prevention. The latter goal can be attained only by identification of those pathogenetic factors that can be modified.

OUTCOME AND MANAGEMENT

Outcome of periventricular-intraventricular hemorrhage is related to six major factors. These include the following: (1) the neurological injury caused by preceding hypoxic ischemic insult or insults; (2) the degree of intracranial hypertension and resulting impaired cerebral perfusion that accompany the larger lesions; (3) destruction of periventricular white matter from intracerebral extension of blood; (4) destruction of germinal matrix (and its glial precursors) by the hemorrhage; (5) focal brain ischemia secondary to vasospasm; and (6) posthemorrhagic hydrocephalus. Initial data indicate a close relation between severity of the hemorrhage and neurological outcome. Infants with lesions of slight or moderate severity are normal on relatively short-term follow-up in the majority of cases. Infants with severe hemorrhages are normal on relatively short-term follow-up in only a small minority of cases.

Management must begin with the ethical decision of whether or not to treat. This critical issue requires careful consideration of clinical and brain imaging data. Cerebral perfusion must be maintained, and this will require maintenance of adequate blood pressure and, if necessary, lowering of increased intracranial pressure. Cerebral overperfusion must be prevented, especially because of the impaired vascular autoregulation. Thus, arterial hypertension, hypercapnia, hypoxemia, acidemia, and rapid infusion of hyperosmolar solutions or

colloid should be avoided. Diligent support of temperature, ventilation, and metabolic status is critical. Moreover, serial assessment of ventricular size by sonar or CT scans is necessary to detect ventricular dilation, which appears before clinical signs.[11] Therapy for posthemorrhagic ventricular dilation is reviewed in detail elsewhere.[1]

CONCLUSION

In the past five years there have been several major advances in the study of neonatal periventricular-intraventricular hemorrhage, eg, the advent of the CT scan, the recognition of the importance of the distribution and the regulation of cerebral blood flow in the newborn, and, now, the use of real-time ultrasonic scanning. The value of the latter in recognition of periventricular-intraventricular hemorrhage is demonstrated superbly by the study of Allan et al, found elsewhere in this issue. This role for ultrasonic scanning should prove to be very important. However, perhaps still greater value will accrue from application of this technique to research directed toward understanding of those factors that lead to this extremely frequent and serious lesion. At least some of these factors may be modifiable, and such modification could result in prevention of many cases of periventricular-intraventricular hemorrhage. Should this occur, ultrasonic imaging of the intracranial cavity will prove to be one of the most important advances ever made in the study of this hemorrhage.

'Teach a Man to Fish' (Chinese Proverb)

A number of commentaries have been published by physicians who have worked with Cambodian refugees. The dimensions of that human tragedy, sensationally, if tardily, emblazoned into our consciousness by the press last fall, elicited a remarkable and heartening response from the world community, a response that greatly alleviated the impact of the massive, acute starvation. Medical personnel from many countries participated in this effort. I was part of a team of two physicians and three nurses, sponsored by the American Baptist Convention, which served in Kamput, a small camp in southeast Thailand. Following are a few personal reflections on this uniquely moving experience.

We arrived in Kamput in early January 1980 after the horrendous death rate due to acute starvation had abated. Some sequelae of malnutrition persisted among the Khmer Rouge who populated Kamput, but its most devastating impact was apparent only when the "population pyramid" of the survivors in the camp was examined. Less than 2% of the population was under 5 years of age, less than 5% under 12. Those too young or too old to have made the harrowing journey under their own power through mountains, jungle, and Vietnamese guns, or too heavy to be carried, did not survive. Those who had been severely malnourished when they arrived were either improved, or dead. Therefore, most of those remaining were likely to be fundamentally robust adolescents and young adults with very few chronic diseases—a grizzly illustration of the principle of survival of the fittest.

Approximately 20% to 30% of all the medical problems seen during that period were the result of falciparum malaria. Also commonly seen were respiratory or gastrointestinal tract illnesses, parasites, and skin eruptions, particularly scabies. Iron deficiency anemia was the most frequently encountered nutritional disease,

with some patients showing residual signs of kwashiorkor or beriberi, but with only rare instances of xerophthalmia among this vegetable-eating people. Tuberculosis was not as common as had been anticipated, and few tropical diseases were seen, or if they were, they were not recognized, given the diagnostic limitations of that very basic facility.

After observation of hundreds of outpatients during a few weeks, certain unexpected patterns of complaints began to emerge. Relatively trivial respiratory symptoms, objectively unverifiable "swelling" of legs, headaches already under treatment by square patches of tape over the temples, and vague complaints of fatigue and abdominal discomfort brought patient after patient to the outpatient facility. Being hampered by the language barrier, our earnest but hastily trained Khmer translators were unable to shed much light on the causes of the complaints, or to transmit our inept efforts at the kind of supportive explanations and advice we would normally use in talking to our patients in this country. We found we had stumbled into a trap. Symptoms were treated with a medication—antihistamines, aspirin, cough preparations, vitamins, or whatever could be rationalized as a justifiable response to the complaint. The message was clear to the patients—if the physicians give a medicine for every symptom, then every symptom must need a medicine. We were essentially giving placebos without that most necessary ingredient of the placebo effect—a physician-patient relationship. Predictably, we generated a "revolving door," which was poorly serving both physicians and patients.

CULTURE LAG

There is no great mystery to the cause of these vague symptoms. As actual survival became less of an issue, depression set in, even in the relative comfort of that camp. Few families are intact. Many had seen their loved ones murdered. Their lives seem purposeless and futureless, and even the immediate is characterized by boredom and punctuated by fear of what "repatriation" may mean for them. The psychosomatic manifestations of depression clearly are not confined to our Western society. However, that does not mean that Western physicians are qualified or even eligible to treat depression in a culture in which they are aliens. The introduction of Western medicine to a people unlikely to have a continued future exposure to its "advantages" raises some serious ethical questions.

This is only one example of the many problems of attempting to reach across the world to "lend a hand." However well-meaning we may be, when we go on short notice in response to an emergency, we go in ignorance. We arrive on the scene as "saviors" from the West, honorably motivated perhaps, but very likely to impose our views and our methods on a people with traditions and perspectives different from our own. When the death rate in camps is one per 1,000 per day because of disease and starvation, as was the case in November 1979, the skills, energies, and resources needed are the lifesaving ones. Once the situation is more subacute and chronic, we need to look carefully at more subtle issues if we are genuinely intent on being of help. There must be sensitivity and respect for the history, culture, and beliefs of the people we are serving and an understanding of the genesis of their current situation. For example, the Khmer Rouge, whether guerrillas or unwilling followers, are uneducated peasants, brutalized, both as perpetrators and victims, by an extraordinary complexity of political events about which they have little knowledge and over which they have no control.

Historically, the ethnic Khmer are a gentle, hospitable people, at one time in their early history the dominant and most sophisticated culture of Southeast Asia; but for 800 years, they and their neighbors have been in conflict. In this century, Western intrusion has complicated their circumstances. Our military incursions played a major role in the disruption of that nation's agriculture, in the creation of millions of refugees, and in the preparation of the ground for takeover by Pol Pot's forces and the virtual destruction of the society. Not to have some knowledge of these factors is not to understand the individual Khmer who emerges from the Kampuchean jungle and the Vietnamese artillery fire 11 km away, a hostile, suspicious, and frightened adolescent, who in a short lifetime has seen and been personally involved in horrors most of us cannot imagine.

We must also appreciate the apprehension of the unwilling host country, Thailand, with its own enormous economic problems and medical needs. For whatever humanitarian reasons, world opinion forced them into a position of harboring an ancient foe, with a concern that another ancient foe, the Vietnamese, would use the sanctuaries as an excuse to invade Thai territory in pursuit of their Khmer Rouge quarry. In close proximity to their own desperately needy peasant villages, the Thai see the Khmer being well-fed and ministered to by the world community. International organizations do not have the mandate to render aid to the Thai. However, voluntary agencies were free to do so, and our own team, with the aid of the Thai Marines and Thai Red Cross, established a traveling outpatient clinic that visited some dozen Thai villages near the Kampuchean border on a rotating basis, but this effort could be little more than gestural considering the dimensions of the need.

The host countries in this "age of the refugee" are indeed in a dilemma. As the world's interest flags, they are likely to be left with the responsibility of supporting a population of homeless aliens who are more comfortable in the refugee camps than in their own, still tumultuous villages back home. The sometimes ruthless efforts by the host to make life less comfortable, or to force repatriation despite its certain hazards to the refugees, should not be entirely beyond our understanding even though it may offend our sense of humanitarianism.

FUTURE MEDICAL RESPONSES

Some questions are being raised about the improvisational nature of the medical response to such emergencies. There were problems at the high-

er administrative levels that proved frustrating to those at the actual interface with the refugees, where there was good cooperation among agencies, and where an international comradery developed that essentially ignored the territorial concerns of higher echelons.

With the experience gained from disasters occurring around the world, some specific procedural and organizational issues should have been already defined, particularly those relative to public health and preventive medicine. At Kamput for example, protocols for immunizations and for the treatment of tuberculosis had to be created as though this were a new and unique situation, with few already established guidelines. Organizations like the International Red Cross have established methods of responding to an acute disaster, but comparable groups are needed to achieve the same kind of structured response during the much longer transitional and rehabilitative period, when social service, educational, vocational, and resettlement issues become the predominant concerns. In generating a medical response to the world's disasters, we must go beyond impulsive and dramatic overseas adventures which, though often enormously helpful, do not address needs beyond those of the immediate, life-threatening crisis. The old Chinese saying, "give a man a fish and you give him a meal, teach a man how to fish and you give him a living," was never more apt. We must establish a means, a sensitivity, an immediate capability to share our enormous wealth of skills and materials effectively and for as long as necessary, in a way which taps the full resources of the population being served while remaining sensitive to its special attributes. The optimal patient-physician relationship, in my view, is one in which both the patient and the physician combine the best of their resources in addressing the problem at hand. We must think in terms of such a therapeutic alliance in our efforts to help less fortunate countries.

Such an informed, responsive posture does not develop in our profession without planning, and this must start at the level of medical education. Most of us are aware that a small percentage of the world's people consume more than half of the world's goods. Most of us know that $100 a person a year is spent on health care in developed countries, and only $1 per person per year is spent in developing countries: that 650 of every million children under 5 years of age die per year in developed countries as compared with 48,000 per million children under 5 in developing countries.[1] It is essential that our medical schools develop an institutional milieu that impresses this kind of stark reality on the consciousness of students and that fosters the development of a broader perspective of the world's medical problems. The student enters medical school idealistic and soon finds he must begin to focus his field of study to more manageable dimensions. With the narrowing of his field, there may be a narrowing of his vision and of his idealism. Lectures and articles are inadequate to counter this trend. There needs to be the possibility for students and residents to become immersed in the mainstream of some of the world's suffering, perhaps working side by side with some of their own faculty, or providing training for individuals from developing countries within their own institutions. Obviously, only a selected few would elect such experiences, but the supportive involvement of the institution establishes a model, and transmits to students and to the community a profoundly important message; that we endow what we teach with the humanity that should characterize our profession.

Can these vital educational concerns, and the devastating medical needs of the world, somehow be brought together in a manner that serves both with dignity and effectiveness? This may well rank beside "what is the future role of the pediatrician" as a question to be addressed in the 1980s.

Sector Scan Ultrasound Imaging Through the Anterior Fontanelle

Its Use in Diagnosing Neonatal Periventricular-Intraventricular Hemorrhage

Walter C. Allan, MD; Christopher A. Roveto, MD; Louise R. Sawyer; Sherry E. Courtney, MD

• The ultrasound sector scanner was used to visualize intracranial pathologic conditions in neonates. The scan head is small enough to make good contact with the anterior fontanelle of infants as small as 700 to 800 g. Clotted blood is clearly seen as a white, echo-dense area, and the scan quality approaches that of computerized tomographic (CT) scan in neonates with intracranial hemorrhage. Three cases were analyzed with CT scan or by autopsy correlation of sector scans. Clinical applications include the diagnosis of periventricular-intraventricular hemorrhage, posthemorrhagic hydrocephalus, and other intracranial pathologic conditions. The use of ultrasound in the diagnosis of neonatal intracranial hemorrhage is briefly reviewed.

(*Am J Dis Child* 134:1028-1031, 1980)

The detection of periventricular-intraventricular hemorrhage has become a major problem in neonatology.[1,2] Prospective studies using computerized tomographic (CT) scans have shown the incidence of hemorrhage to be approximately 40% in all infants of less than 35 weeks' gestation.[3,4] The diagnosis of hemorrhage is made urgent by the high incidence of posthemorrhagic hydrocephalus and the fact that the extent of hemorrhage has been shown to correlate with prognosis.[5] Thus, detection of hemorrhage at an early stage may allow early therapy for hydrocephalus and may aid in decision making in treatment of severely ill infants.

The diagnosis of hemorrhage is difficult since clinical signs can be absent even in the face of moderate to marked hemorrhage. Although CT scanning reliably demonstrates hemorrhage, it is expensive and exposes the critically ill infant to unneeded risks. For these reasons, we have been interested in finding alternate methods of detecting periventricular-intraventricular hemorrhage.

For editorial comment see p 1023.

Recently, reports have appeared describing linear-array, real-time ultrasound scanning in preterm infants.[6-8] The resolution of published images, however, is limited by bone artifact. Cooke[9] suggested that better resolution could be obtained using the sector scanner and imaging through the anterior fontanelle.

Because the scanner is portable, the scan can be done without disturbing the infant at bedside. In addition, the infant's movements do not detract from the image quality. Thus, the problems of transportation, support, sedation, and exposure to ionizing radiation inherent in CT scanning are avoided. The image quality seems superior to published examples of linear-array ultrasound scans and promises to be as accurate as CT scanning in establishing the presence and extent of hemorrhage. We report our experience in using the sector scan in three illustrative cases with autopsy or CT scan correlation of all sector scans.

MATERIALS AND METHODS

Sector scans were performed at bedside with a real-time digital scan controller using the 5-MHz, three-crystal arc scan head. All scans were done through the anterior fontanelle, with the scan head directly touching the fontanelle after ultrasonic gel was applied. The sector scanner sweeps a field subtended by a 90° arc to varying tissue depth with three rotating pulser receivers. It produces a real-time, two-dimensional image that is recorded on videotape. The scan head is small compared with linear-array transducers. An area as small as 1 sq cm will produce good contact.

This allows one to use the anterior fontanelle of even 700- to 800-g infants. By changing the plane of the scan head, coronal and sagittal images of high resolution that are devoid of bone artifact can be obtained. Scan time was usually five minutes for both a coronal and a sagittal sweep. The scan was recorded on videotape, and various portions were freeze-framed to make illustrations for this article. The CT scans were obtained in the radiology department.

Hemorrhage is demonstrated by its echo density and by the mass effect it produces. When clotted blood is present, a white, echo-dense area is noted. Prior to clot formation, blood is not as white but makes the ventricular walls indistinct by its intermediate echo density. Periventricular blood can be distinguished not only by its density but by displacement of the walls of the ventricle.

Early in our experience, we correlated the location and size of the hemorrhage shown in the ultrasound images with CT scans or with autopsy in each infant in whom abnormal findings were made. After the first six infants, we no longer believed that this was necessary since hemorrhage and intracranial anatomy were clearly demonstrated by sector scan. We could reliably identify normal structures by their position or their vascular pulsation. The lateral ventricles, interhemispheric fissures, and Sylvian fissures were immediately apparent. In addition, we routinely saw the pericallosal arteries, the cavum septum pellucidum, the third ventricle with its infundibular and chiasmatic recesses, and the fourth ventricle. Certain structures produce increased echoes resembling clotted blood. The structures most likely to produce confusion with periventricular hemorrhage are the head of the caudate and the lateral nuclei of the thalamus. These are echo-dense periventricular structures.

PATIENTS

The three illustrative cases were taken from a group of 62 infants who were admitted to the Maine Medical Center Neonatal Intensive Care Center (MMC-NICC), Portland, between September 1979 and January 1980. We performed a total of 103 scans on these infants for diagnosis and follow-up observation of periventricular-intraventricular hemorrhage. Forty-eight infants were of 35 weeks' gestation or less, and 29 weighed 1,500 g or less. Fourteen full-term infants were also scanned.

We detected 12 hemorrhages in this group, ranging from mild periventricular to large periventricular and intraventricular hemorrhage (grades 1 to 4 of Papile et al[3]). Posthemorrhagic hydrocephalus occurred in four. Three infants died. Other diagnoses made with the sector scan in this group included congenital hydrocephalus in two infants and multicystic encephalomalacia in one.

REPORT OF CASES

Case 1.—A 1,360-g female infant of 30 weeks' gestation was transferred to the MMC-NICC on the first day of life. She had Apgar scores of 0 and 1 at one and five minutes of age. On arrival, the infant had an ashen color but had spontaneous movements. Despite vigorous support, the infant had become stuporous by 18 hours of age and frequent seizures had developed. A sector scan of the brain at 24 hours of age showed bilateral intraventricular hemorrhages. Support was discontinued with parental consent and the infant died. Autopsy confirmed the findings on sector scan (Fig 1 and 2).

Case 2.—A 1,120-g female infant of 30 weeks' gestation was transferred to the MMC-NICC within one hour of birth. The Apgar scores were 4 and 6 at one and five minutes of age. On arrival, the infant appeared to be in mild respiratory distress with good peripheral perfusion. On day 2 of life, a lumbar puncture produced bloody, mildly xanthochromic CSF with an elevated protein level. Sector scan and subsequent CT scan demonstrated a large right-sided periventricular-intraventricular and intracortical hemorrhage (Fig 3). Physical examination revealed a vigorous, alert infant without signs of increased intracranial pressure. By 16 days of age, rapid increase in head circumference was noted. Dramatic hydrocephalus was demonstrated by sector scan and was confirmed by CT scan. External CSF drainage was obtained with a right frontal percutaneous ventricular catheter and a sterile collecting bag. The ventricular size, CSF protein content, and cell count decreased during drainage. After seven days the catheter was removed to avoid infection. The ventricular size increased serially over three days as demonstrated by sector scan, and a ventricular catheter was reinserted (Fig 4). The infant required four separate periods of ventriculostomy drainage, with three to five days between without a catheter. This allowed her to grow to 2.4 kg, and a permanent ventriculoperitoneal shunt was placed.

Case 3.—A 1,630-g infant of 32 weeks' gestation was transferred to the MMC-NICC on the first day of life because of respiratory distress. The infant's twin had been delivered vaginally, but the birth canal had become obstructed by the placenta, so this infant had been delivered by emergency cesarean section. Apgar scores were 7 and 9 at one and five minutes of age. On arrival, the infant was in mild distress. On day 3 a sector scan was performed; the area of the head of the caudate nucleus was indistinct, though no hemorrhage could be seen. The scan was repeated at 10 days of age, and a clot was now apparent in the area of the right caudate nucleus (Fig 5 and 6).

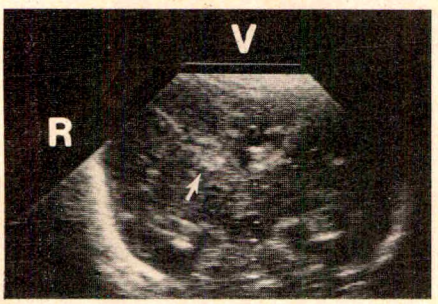
COMMENT

Evidence for the importance of neonatal periventricular-intraventricular hemorrhage comes from recent prospective studies. Papile et al[3] performed CT brain scans on all infants weighing less than 1,500 g during a six-month period. They demonstrated that 43% (20/46) had detectable hemorrhages and graded the hemorrhages by the extent and location of the blood. Clinical evidence of hemorrhage (change in muscular tone and activity, seizures, full fontanelle, hypotension) was more common in infants who died, but some infants with severe hemorrhages survived and had no clinical evidence of hemorrhage.

Similarly, Lazzara et al[4] performed CT scans on all premature infants in their group with a gestational age of less than 35 weeks. They found that 38% (31/81) had hemorrhages. Only half were suspected clinically, and the clinical suspicion of hemorrhage was correlated with marked hemorrhage.

The incidence of posthemorrhagic hydrocephalus in these infants was also studied. Papile et al[3] found that hydrocephalus developed in 44% and Ahmann et al[10] found a 26% incidence of this complication. It was possible to further grade the infants who had hydrocephalus by the extent of the original hemorrhage. Papile et al found that hydrocephalus developed in no infants with grade 1 or 2 hemorrhage, but all surviving infants with grade 3 or 4 hemorrhage demonstrated this complication.[3] Ahmann et al found that the original hemorrhage in those infants in whom hydrocephalus developed was marked in 75%, moderate in 15%, and mild in 5%.[10]

Thus, hemorrhage is common, clinically silent for the most part, and frequently associated with hydrocephalus. The studies cited suggest that



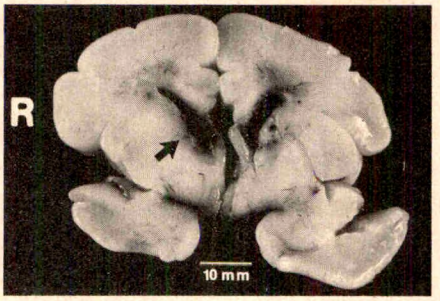


Fig 1.—Left, Coronal sector scan done at 24 hours of age in case 1. V indicates vertex, R, right side. Increased echoes can be seen in right lateral ventricle and periventricular area (arrow). Left lateral ventricle also has increased echoes in it and possibly also in periventricular area. It is not completely obscured, and echo-free area of normal ventricle is noted. Area of third ventricle is deformed and indistinct with increased echoes compared with surrounding brain suggesting that it, too, is filled with blood. Compare with figure on right for anatomical landmarks. Right, Autopsy specimen at approximately same plane as sector scan, left. Note periventricular hemorrhage inferior to right lateral ventricle (arrow). Third and both lateral ventricles contain blood clots.

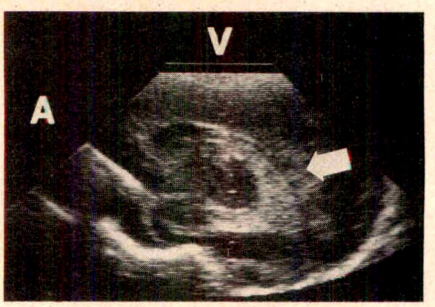

Fig 2.—Sagittal sector scan; image was obtained by angling scan head from anterior fontanelle toward infant's right until sweep of entire right lateral ventricle was seen. V indicates vertex, A, anterior. Note that walls of dilated right lateral ventricle are clearly seen from frontal horns to occipital and temporal horns (arrow). Ventricle is almost completely filled with blood, producing increased echoes.

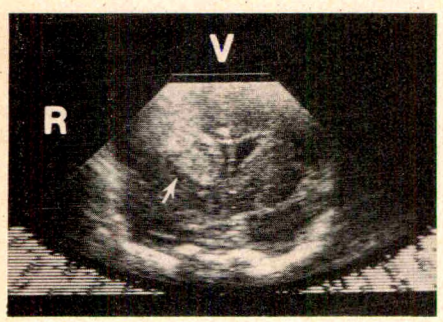

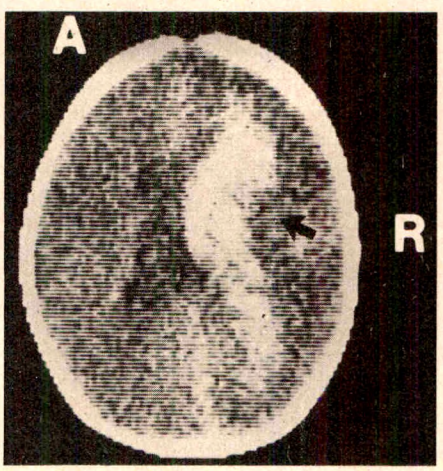

Fig 3.—Left, Coronal sector scan obtained on third day in case 2. V indicates vertex, R, right side. Large periventricular, intraventricular, and intracortical clot can be seen as area of increased echoes in right hemisphere (arrow). Left ventricle is free of echoes and is dilated. Right, A indicates anterior. Computerized tomographic scan obtained same day shows large right-sided hemorrhage and dilated left ventricle (arrow).

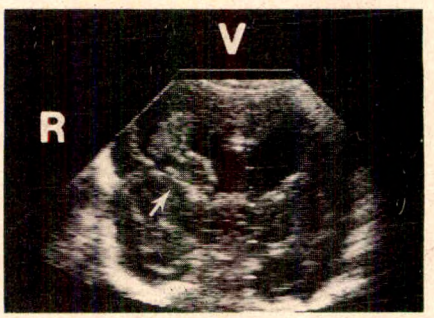

Fig 4.—Coronal sector scan obtained at time of insertion of second ventricular catheter in case 2 (see "Report of Cases"). V indicates vertex, R, right side. Compare with Fig 3, left. Ventricles are dilated and right ventricle shows resorbing clot and developing porencephalic cyst (arrow). Computerized tomographic scan done same day failed to reveal clot.

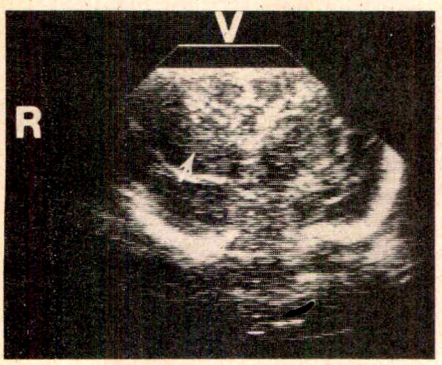

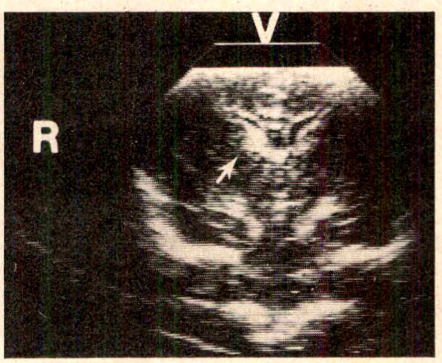

Fig 5.—Left, Coronal sector scan obtained day 3 in case 3. V indicates vertex, R, right side. Area of caudate head (lateral margin of ventricles) is indistinct and ventricles are obscured bilaterally (arrow). Right, Repeated scan obtained on day 10 in case 3 shows clot in periventricular area, now an area of increased echoes (arrow). Right lateral ventricle is mildly deformed by mass effect.

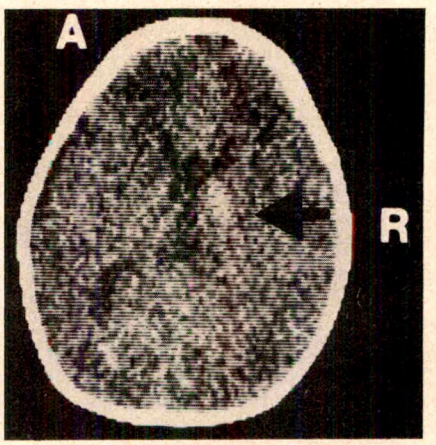

Fig 6.—Computerized tomographic scan in case 3. A indicates anterior, R, right side. Small periventricular hemorrhage seen on sector scan is apparent, right (arrow).

this complication would occur in more than 10% of all neonates of less than 35 weeks' gestation. Although the procedure of CT scanning established these data, its general application to all neonates of less than 35 weeks' gestation has not, to our knowledge, occurred, and recent investigators have looked for other methods of imaging.

Pape et al[6] recently reported their experience in using linear-array, real-time ultrasound scanning in 31 infants of less than 33 weeks' gestation. Dense opacities filling the ventricular system developed in four infants and were confirmed to be hemorrhages by CT scan and by autopsy. Johnson et al[7] studied 41 premature infants, using linear-array, real-time ultrasound scanning and correlated their findings with CT scan. Not all patients had both studies performed, and in only four patients was intraventricular blood clot demonstrated by linear-array ultrasound. Johnson et al did find a high correlation ($r = .99$) between CT scan and ultrasound measurements of ventricular size in 12 infants in whom post-hemorrhagic hydrocephalus developed. Silverboard et al[8] prospectively studied the correlation between linear-array ultrasound and CT scans in 40 infants. Sixteen had hemorrhages that were diagnosed by CT scan (8 marked, 5 moderate, and 3 mild). Ultrasound scan predicted the hemorrhage in all but two infants with mild hemorrhage. Linear-array ultrasound scan uses a transducer that is too large to make a good fit on the anterior fontanelle of small infants. Most scanning is done through the parietal bone and this introduces artifact.

To our knowledge, ours is the first report to show sector scan ultrasound images of periventricular-intraventricular hemorrhage. Our three cases provide evidence for excellent correlation between sector and CT scans as well as for the actual pathologic conditions seen at autopsy. What is more, as mentioned in the legend to Fig 4, the sector scan can show clots that are "isodense" on CT scan. The periventricular region is well seen on the sector scan, but other areas of white matter and of cortex are better visualized by CT scan. Thus, sector scanning has not supplanted CT scanning at our hospital except in screening for periventricular-intraventricular hemorrhage.

We have not prospectively demonstrated that sector scanning is as accurate as CT scanning in instances of mild hemorrhage (ie, hemorrhages confined to the periventricular area). Still, case 3 illustrates such a hemorrhage on sector scan in the head of the caudate nucleus. As Volpe has emphasized, 75% to 90% of hemorrhages originate in the subependymal germinal matrix at the level of the foramen of Monro and the head of the caudate.[2] This is an area particularly well visualized by the coronal sector scan. Thus, theoretically, sector scanning should provide the accuracy of CT scanning in periventricular hemorrhage. However, as illustrated in case 3, the timing of the scan may be critical.

We believe that we have demonstrated the usefulness of static images obtained by sector scanning. However, the scanning is in fact done in real time, and this offers a further advantage. Pape et al[6] have emphasized the advantages of real-time imaging in neonates. They have noted waxing and waning pulses in the choroid plexus and arteries during the evolution of infarction. Although the implication is that loss of pulses may reflect severe decreases in cerebral blood flow, the study of this phenomenon is only beginning. Bada et al[11] have used Doppler recordings through the anterior fontanelle to study intracerebral vascular resistance in asphyxiated neonates. Interestingly, they found decreased resistance to flow in the first 48 hours of life that changed to increased resistance at the time of hemorrhage in preterm infants.

Other research uses that have occurred to us would take advantage of the possibility of doing multiple scans at frequent intervals. This would establish the timing of hemorrhage more accurately and would permit closer scrutiny of various iatrogenic factors such as sodium bicarbonate administration. At present, the sector scanner is being used actively at our hospital to screen all infants of less than 35 weeks' gestation for hemorrhage.

Harold Osher, MD, and Martha Foster, MA, assisted in the preparation of the manuscript.

Reye's Syndrome in Three Siblings

Association With Type A Influenza Infection

Rickey Wilson, MD; Jenelle Miller, MD; Harry Greene, MD; Robert Rankin, MD; Lawrence Lumeng, MD; David Gordon, MD; David Nelson, MD; Gary Noble, MD

• Reye's syndrome occurred simultaneously in three siblings. All had characteristic changes in liver histology ascertained by light and electron microscopy. The two patients with the most severe disease also had serum that caused marked stimulation of mitochondrial state 4 respiration in vitro. Histocompatibility locus antigen typing showed that no unique haplotypes were shared by all three children. There was no evidence of exposure to aflatoxins, pesticides, or other substances that have been previously postulated to be associated with Reye's syndrome. Influenza A/Brazil/11/78-like virus was isolated from one patient, and all three patients had a fourfold or greater rise in hemagglutination-inhibiting antibody to H1N1 influenza virus.

(*Am J Dis Child* 134:1032-1034, 1980)

Despite reports of increased attack rates of Reye's syndrome for siblings of patients who have the disease,[1] it rarely affects family groups. In the few instances in which multiple cases have occurred in one family, a common, underlying predisposition or a common exposure has been postulated. Pursuing this line of reasoning, investigators have studied histocompatibility locus antigen (HLA) typing,[1] exposure to hepatotoxins,[2-5] and exposure to viral agents[6-9] as possible common factors causing Reye's syndrome to affect siblings. We describe our epidemiologic and clinical investigations of three siblings in whom Reye's syndrome developed concurrently.

PATIENTS

Table 1 summarizes the illnesses of the three children. Within 24 hours, all had rapid onset of vomiting followed by a change in neurologic status. All three children had an antecedent respiratory illness from which all were uneventfully recovering. Patients 1 and 2 had a more severe illness, which necessitated subarachnoid pressure monitoring and intravenous mannitol to control cerebral edema. After 48 to 72 hours, all three patients showed rapid improvement in clinical status and were discharged after one week of hospitalization. None had any evidence of neurologic deficits at discharge.

MATERIALS AND METHODS

We reviewed hospital records in the referral hospital in Chattanooga, Tenn, from January 1975 to January 1979 to determine the number of patients with Reye's syndrome who were admitted to this hospital. We noted city of residence, date of admission, method of diagnosis, clinical management, and possible relationship to other patients with Reye's syndrome. We interviewed the family members of the three patients and obtained a detailed family medical history for three generations. We questioned family members for any evidence of current family illness and any history of illness that might be compatible with Reye's syndrome.

We visited the three dwellings in which the ill children had stayed for at least one day during the month prior to hospitalization. A careful visual search was made for pesticides, household chemicals, and medicines that might be hepatotoxic. The location of each house in relation to fields that might have been sprayed with pesticides was also determined. We checked the areas near the homes for barns, silos, or other storage facilities that might contain moldy grain or corn and thus be a potential source for aflatoxin. We also visually inspected the water supplies and toilet facilities in the residences under investigation. Sources of heat (ie, coal, wood, gas, charcoal) for these buildings were also investigated to determine whether exposure to potentially noxious gases might have occurred.

Closed percutaneous liver biopsy specimens were obtained on Jan 30 (patients 1 and 2) and 31, 1979 (patient 3) and examined by light and electron microscopy. Biopsies were performed on patients 1 and 2 while they were still comatose. Biopsy was performed on patient 3 one day later to confirm the suspected diagnosis of Reye's syndrome, though her neurologic status did not show the same degree of deterioration as did the neurologic status of patients 1 and 2. All three patients had throat and nasal viral culture taken by swab on Feb 1. Acute- and convalescent-phase serum specimens were obtained on Jan 30 and May 31, respectively, for testing for antibodies to respiratory viruses and were tested by hemagglutination inhibition (HI)[10,11] for antibodies to influenza virus. A fourfold or greater rise in antibody titer was considered diagnostic. Serum specimens from the three children were also tested for their in vitro effect on state 4 respiration (change in nanograms of oxygen released per minute) of a rat's liver mitochondrial preparation. A minor modification of the method of Aprille and Asimakis[12] was used in which 10 μL of a

fivefold-concentrated serum specimen was placed in 2 mL of incubation medium. Blood specimens obtained from the three children and their father were tested for lymphocyte stimulation using several mitogens, including phytohemagglutinin, pokeweed mitogen, and *Candida*. Levels of serum immunoglobulins were measured, and HLA typing[13] was also performed on the three children and their father. Blood and urine samples from all three children were also tested for the presence of barbiturates, salicylates, heavy metals, and phenothiazines.

RESULTS

Excluding the three siblings in this report, eight cases of Reye's syndrome were diagnosed since 1975 at the referral hospital. Only two of these children were from the same geographic area as the children discussed in this report. Four of the eight children had died. Four cases were associated with chickenpox, and none had occurred in siblings.

A detailed family medical history did not identify any children in the extended family with an illness compatible with Reye's syndrome. There had been only one unexplained death in the past three generations, and the history was compatible with sudden infant death syndrome.

The three homes examined had public water, indoor toilet facilities, and natural gas for heating. No pesticides or common household cleaning agents were located in any cabinets accessible to the children. No family members were taking any prescription drugs, and other medications were kept in a locked cabinet. There were no cultivated fields in the immediate vicinity of any of the homes. There were no barns, silos, or other storage facilities for grain or other material that might have been a source of aflatoxin exposure.

Light microscopic examination of all three liver biopsy specimens revealed microvesicular fatty infiltration. Electron microscopy revealed mitochondrial swelling in all three specimens, but only specimens from patients 1 and 2 revealed mitochondrial disruption. When serum samples from the three patients were tested for in vitro stimulation of state 4 mitochondrial respiration, the two patients with the most severe abnormalities seen clinically and by electron microscope (patients 1 and 2) were found to be stimulatory. The same preparation of isolated rat's liver mitochondria was employed to obtain valid comparisons. In four control subjects, the increase in state 4 respiration was 0.10 ± 0.10 ng of O_2 per minute (mean ± 1 SD); in patient 1 it was 0.94 ng/min; in patient 2, 2.35 ng/min; and in patient 3, 0.24 ng/min.

Urine and blood toxicologic screening on all three children failed to reveal evidence of drug ingestion. There was no history of salicylate ingestion. Immunoglobulin determinations and results of lymphocyte stimulation studies were normal. Analysis of HLA typing for all family members gave the following results: for the father, A28, B40/Aw24, B "blank"; for the mother (as hypothesized, since she had died), A3, B15/Aw19, B12; for patient 1, Aw19, B12/Aw24, B "blank"; for patient 2, A3, B15/Aw24, B "blank"; and for patient 3, Aw19, B12/A28, B40. No haplotype segregation was evident.

No increase in complement-fixing antibodies to coxsackie virus B types 1 to 5, to adenovirus group antigen, or to *Mycoplasma pneumoniae* was observed in the sera for any of the three patients with Reye's syndrome. All three patients, however, had a four-

UNIVERSITY OF CALIFORNIA LIBRARY

fold or greater rise of HI antibody to the closely related influenza A (H1N1) antigenic variants A/USSR/92/77 and A/Brazil/11/78 when paired, acute- and convalescent-phase serum specimens were tested (Table 2). Influenza A/Brazil/11/78-like virus was isolated from a throat culture of patient 1 taken on the fifth day of illness.

COMMENT

We have reported the simultaneous occurrence of Reye's syndrome in three siblings. Not only were all clinical and laboratory criteria for Reye's syndrome met as defined by the Center for Disease Control, Atlanta,[14] but all patients had liver biopsies performed with the characteristic findings of microvesicular fatty infiltration on light microscopy and mitochondrial swelling on electron microscopic examination.[15] The two most severely affected patients had mitochondrial disruption on electron microscopic examination of their liver biopsy specimens and also had serum that was stimulatory to state 4 mitochondrial respiration in vitro. Aprille and Asimakis[16] and Lumeng et al[17] have found that sera from patients with Reye's syndrome contain a low-molecular-weight, heat-stable molecule that interacts with site III of the mitochondrial respiratory chain. The degree of stimulation in each of our patients correlated with the clinical severity of illness.

We could find no environmental factors to explain the simultaneous occurrence of disease in the three children. Though toxins and pesticides have been postulated to play a role in the development of Reye's syndrome, we did not discover exposure to chemicals in these patients. Except for the unlikely event of untested C- or DR-locus antigen associations, there is no evidence of haplotype segregation by HLA typing. These findings are in accord with those of Hilty et al.[1]

Clinical history, culture results, and serologic data all indicate that an H1N1 influenza viral infection was the antecedent event common to all three patients. Earlier reports have linked antecedent types A and B influenza infection with the onset of Reye's syndrome.[6-8] During the winter of 1978 to 1979, there was evidence of a nationwide outbreak of type A influenza (H1N1) virus among children and the concomitant appearance of Reye's syndrome in areas of type A influenza activity.[18]

This episode illustrates the necessity for careful search, not only for potential genetic and environmental factors that might predispose one to the development of Reye's syndrome, but also for infectious agents. Obtaining cultures for viral agents and testing acute- and convalescent-phase serum specimens are necessary to a thorough investigation of these clusters. Though there are reports that Reye's syndrome has occurred in contacts of patients with Reye's syndrome,[9] there is no direct evidence that it is a contagious disease. However, as is illustrated by this cluster of cases, a common exposure to an infectious agent may result in multiple cases of the disease in one family. The HLA typing did not reveal haplotype segregation. Though there may be other underlying genetic factors that predispose siblings in some families to acquiring Reye's syndrome, HLA typing was not fruitful in this investigation. Continued investigations of genetic, environmental, and infectious diseases to determine the etiology and pathogenesis of Reye's syndrome are necessary.

Long-Limbed Campomelic Dwarfism

A Radiologic and Pathologic Study

Garth E. Austin, MD, PhD; Richard H. Gold, MD; Joseph M. Mirra, MD; Sheryl Perry, MD; Sri Moedjono, MD

• **Comparison of the roentgenographic and pathologic features of a case of classic, long-limbed campomelic dwarfism with those of previously reported cases leads to the conclusion that the bony abnormalities in this disorder are not due to an intrinsic abnormality of cartilage formation or of osteoblast or osteoclast function. Likewise, no defect in bone collagen, ground substance, or mineralization is evident. The bowing of the long bones may be the result of poorly understood muscular stresses operative in utero. Widespread defects in other organ systems are present, with considerable variation from patient to patient. Phenotypic females with the disorder commonly suffer from gonadal dysgenesis. Autosomal recessive inheritance is suggested for a subgroup of these patients, but environmental factors may be causative in some instances.**

(*Am J Dis Child* 134:1035-1042, 1980)

The campomelic syndrome is a rare form of congenital short-limbed dwarfism characterized by prenatal bowing of the long bones of the lower extremities and is associated with a number of other anomalies of the skeletal system and the CNS.[1,2] Khajavi et al[3] have recently shown that this syndrome comprises a heterogeneous group of disorders and have subclassified them into three types: (*a*) long-limbed, or classic campomelic syndrome, in which the "bent" bones are of normal caliber and are moderately shortened; (*b*) normocephalic, short-limbed campomelic dwarfism, in which the bones are strikingly shortened and also too wide; and (*c*) short-limbed campomelic dwarfism with severe craniosynostosis. The nature of the bony abnormalities in the classic campomelic syndrome is controversial, and the mechanisms responsible for the bowing of the lower limbs are unclear. Furthermore, the spectrum of extraskeletal abnormalities in this condition remains poorly defined. We present here the roentgenographic and autopsy findings of a case of long-limbed campomelic dwarfism, together with a detailed consideration of the emerging radiologic and pathologic features of this condition.

REPORT OF A CASE

The patient, a 2.4-kg male infant of 36 weeks' gestation (by dates), was born to a 25-year-old, primagravida, Nigerian woman. The parents are nonconsanguineous and were born and raised in different parts of Nigeria. The father was 28 years old when the baby was born. The family history was devoid of short stature, birth defects, mental retardation, and neurologic diseases.

The pregnancy was complicated by an upper respiratory tract infection one week prior to delivery and by maternal hypertension without peripheral edema at 34 weeks' gestation, for which the mother took antihypertensive medication. The mother denied alcohol intake or exposure to ionizing radiation during pregnancy. There was also a history suggestive of polyhydramnios; weight gain during pregnancy was 15 kg, and the uterus was felt to be abnormally large. However, the amniotic membranes ruptured before sonography could be done, and vaginal delivery by low forceps was accomplished 16 hours later. The mother was febrile to 38 °C during this period.

At birth, the baby was noted to have multiple anomalies and was transferred to the UCLA Medical Center. At 1 day of age, the infant weighed 2.5 kg, was 36 cm long, and had a head circumference of 34.5 cm (75th percentile). The anterior and posterior fontanels were of normal size. The infant had a peculiar flat facies with micrognathia, a flat nasal bridge, a slightly elongated philtrum, and low-set but normally shaped ears. The intercanthal dis-

*Refers to patients in 32 cases previously reported where presence or absence of findings could be verified.[1-20]

†Faint ossification of epiphysis seen in postmortem roentgenogram of dissected limb but not in standard roentgenograms.

tance was normal, and there were no ocular abnormalities. Glossoptosis and a midline cleft of the soft palate were noted. The neck appeared short, but no chest deformities were seen, and the spine was straight. Cardiac examination results were normal. The liver was palpable 2 cm below the right costal margin; there was no splenomegaly. Genitalia were those of a normal male with descended testes. Karyotype (performed on lymphocytes) was 46,XY. The anus was patent. The infant was hypotonic, and the Moro, grasp, and suck reflexes were all poor.

Anomalies of the extremities were striking. There was obvious mesomelic shortening of the lower limbs, which were 39 cm long with an upper to lower segment ratio of 2.2 (normal ratio, 1.7). There was pronounced, symmetrical anterior bowing of the tibias with cutaneous dimples over the point of maximal angulation. Less conspicuous bowing of the fibulas and femurs was also noted. There were bilateral varus deformities of the feet. The upper extremities were unremarkable except for mild hypoplasia of the digits and a mild degree of camptodactyly, particularly of the distal interphalangeal joints. Dermatoglyphics were normal.

The baby was in mild respiratory distress and initially required oxygen therapy but was quickly weaned to room air. He continued to have feeding problems secondary to cleft palate and respiratory distress, which appeared to be independent of his glossoptosis. He died at 11 days of age.

ROENTGENOGRAPHIC FINDINGS

The present case manifests many but by no means all of the roentgenographic features described in previous reports of long-limbed campomelic dwarfism[1-20] (Table 1).

Lower Limbs

The characteristic bowing and shortening of the tibiae, fibulae, and femora as observed clinically were confirmed (Fig 1). In comparison with normal standards,[21] all of the long, tubular bones of the lower limbs were severely shortened, the femora by 30% of their normal 50th percentile length, the tibiae by as much as 50% of their normal 50th percentile length, and the fibulae by as much as 70% of their normal 50th percentile length. The femora were sharply bowed anterolaterally near the junction of their proximal and middle thirds. The tibiae were similarly bowed near the junction of their middle and distal thirds. The caliber of both sets of bones remained normal. Along the concave aspects of their curvatures, the bones were extremely dense, being composed of thick spicules oriented along lines of stress in a direction perpendicular to the cortex and radiating so as to converge at the apex of the curve.

Postmortem roentgenography of a dissected lower limb revealed early ossification of the distal femoral epiphysis. The fibulae, though shortened, were not bowed or diminished in caliber. The tali and cuboid bones, which should be ossified to some extent by birth and by 1 month of age, respectively, remained unossified. The calcanei, instead of being pear-shaped, were rectangular and too closely apposed to the tibiae. The metatarsals appeared normal, but the phalanges were too short. Specific views to investigate the varus deformity of the feet were not taken.

Upper Limbs

The humeri, radii, and ulnae, though not bowed and of normal caliber, were shortened by 25% of their normal 50th percentile length.[21] Neither elbow dislocation nor radiohumeral synostosis was present. In the hands (Fig 2), the first and fifth metacarpals and all of the middle and distal phalanges were shortened. Clinodactyly (shortening and in-curving) of the fifth fingers was present.

Spine

The only vertebral abnormality was failure of mineralization of the pedicles of T-6 through T-8. Neither kyphoscoliosis, vertebral flattening, narrowing of the vertebrae, hypoplasia of the lower cervical spine, nor increased interpediculate distances in the lumbar spine[22] were present, though these features had been previously reported in some cases. Abnormal stellate fissuring of the vertebral bodies was not identified; only their normal venous sinus grooves were seen.

Pelvis

The iliac wings were slightly narrowed, but iliac and acetabular angles[23] remained

within normal limits, and the hips were not dislocated (Fig 3). The ischia were oriented in an excessively vertical direction, and the superior pubic rami had failed to mineralize except for a tiny, faint focus of ossification on the left.

Thorax

The ribs were too narrow but numbered 12 pairs. The thorax was of normal shape. The sternum remained unmineralized. The scapulae were not hypoplastic, a finding at variance with all previously reported cases. The larynx and trachea were of normal width (Fig 4).

Skull and Mandible

The skull was not enlarged, but facial hypoplasia was reflected in an interocular distance that was below the tenth percentile for boys 1 year of age or younger.[24] The mandible was mildly hypoplastic (Fig 5).

AUTOPSY FINDINGS

A comparison of the extraskeletal manifestations in our case with those in previously reported cases is given in Table 2.[1-20,25,26] External examination of the body confirmed the presence of congenital abnormalities of the head and extremities as described clinically. There were no abnormalities of the visceral organs. The lungs were congested. The larynx, trachea, and major bronchi were unremarkable. In contrast with several previous reports, the tracheal and laryngeal cartilages were normal. The abnormal CNS findings were absence of the olfactory bulbs, tracts, and striae. Peripheral nerves were histologically unremarkable.

The major muscle groups of the extremities were grossly and histologically unremarkable. Bilaterally symmetrical pretibial skin dimples were noted. They represented depressions within focal bulges of skin and subcutaneous tissue over the apices of the extremely curved tibiae. Histologic examination of the pretibial bulges showed only condensed dermal collagen at this site. The male genitalia were normal both grossly and histologically.

SKELETAL CHANGES

Portions of the skull, lumbar vertebrae, pelvic bones, costochondral junction, humerus, radius, ulna, entire middle finger of the right hand, femur, tibia, and fibula were examined grossly and histologically. Bones of the cranial vault were normal. The tibia was markedly shortened, measuring 43 mm from the center of the proximal articular cartilage to the center of the distal articular cartilage as a straight line. The measurement from the center of the

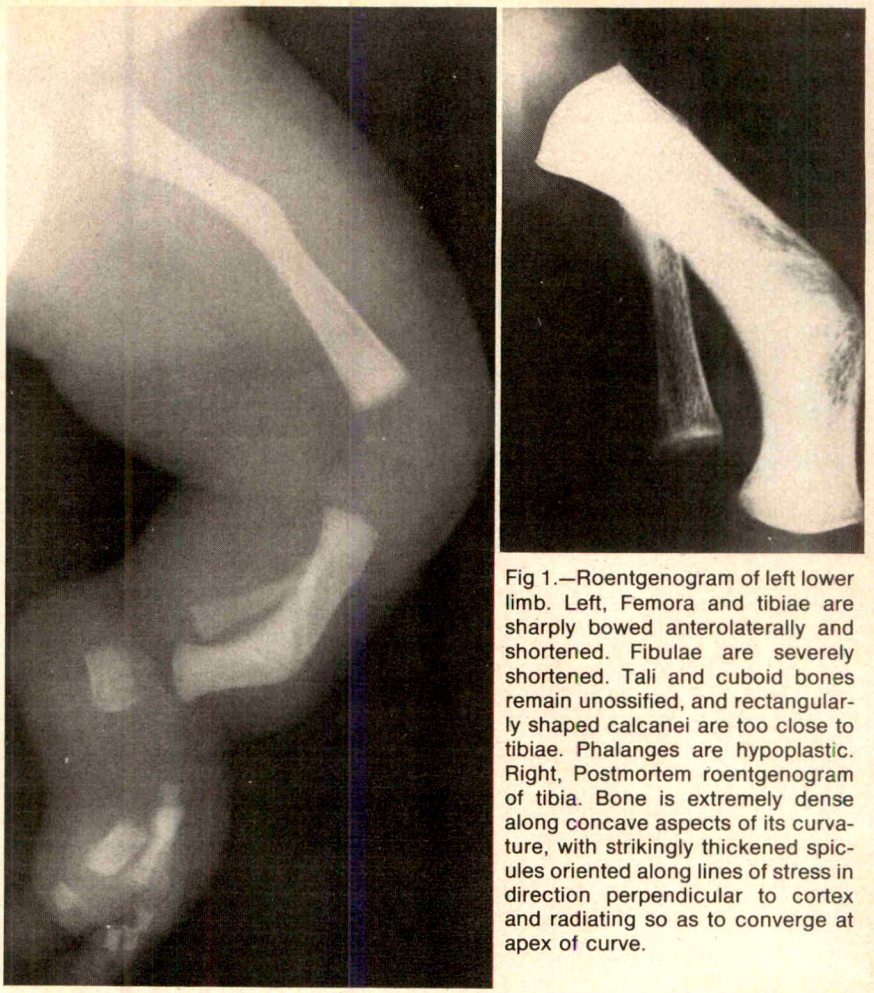

Fig 1.—Roentgenogram of left lower limb. Left, Femora and tibiae are sharply bowed anterolaterally and shortened. Fibulae are severely shortened. Tali and cuboid bones remain unossified, and rectangularly shaped calcanei are too close to tibiae. Phalanges are hypoplastic. Right, Postmortem roentgenogram of tibia. Bone is extremely dense along concave aspects of its curvature, with strikingly thickened spicules oriented along lines of stress in direction perpendicular to cortex and radiating so as to converge at apex of curve.

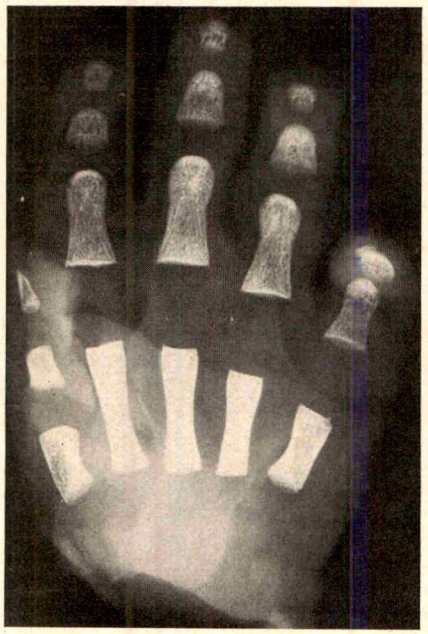

Fig 2.—Postmortem roentgenogram of hand. Shortening of first and left metacarpals, middle and distal phalanges, and clinodactyl of fifth finger.

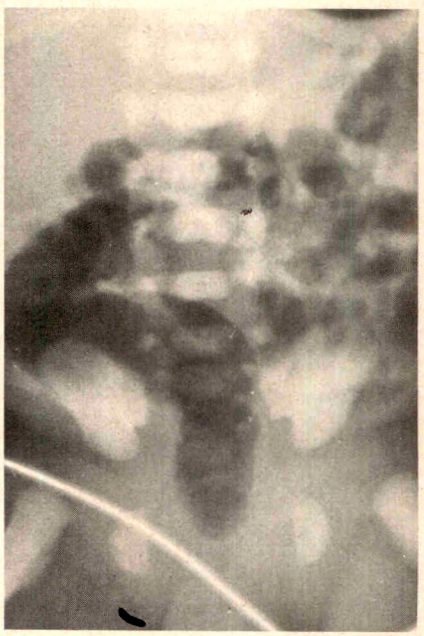

Fig 3.—Roentgenogram of lumbar spine and pelvis. Interpediculate distances are within normal limits. Iliac wings are slightly narrowed. Ischia are excessively oriented in vertical direction. Superior pubic rami have not mineralized.

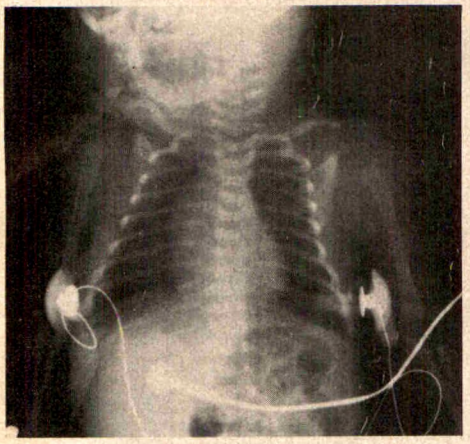

Fig 4.—Roentgenogram of thorax. Ribs are excessively narrow. Shape of thorax is normal. Scapulae are not hypoplastic.

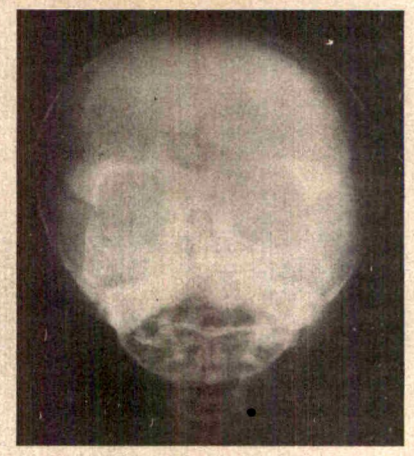

Fig 5.—Roentgenogram of skull and mandible. Anteroposterior view shows severely diminished interocular distance and small mandible.

*Refers to 38 previously reported cases, 18 of which were autopsied.[1-20,25,26]

proximal articular cartilage to the anatomic center of the bone was 27 mm, whereas that from the center of the distal articular cartilage to the anatomic center of the bone was 19 mm. The proximal articular cartilage measured 7 mm in width, and the distal articular cartilage measured 4 mm, at their respective centers. The articular and epiphyseal plate cartilages of the tibia and other bones examined showed no recognizable abnormalities (Fig 6). The columns of cartilage were regular and appeared to be of normal length compared with those of an age-matched control subject. Longitudinal section of the midshaft of the tibia revealed an anterolateral bowing in which long spicules of dense bone originating from the concave aspect of the tibia radiated centrally, creating a pyramidal or dome shape (Fig 7). This abnormal trabecular pattern gradually disappeared in the vicinity of the metaphysis. In cross section (Fig 8), it could be seen that the spicules represented markedly thickened cortical bone with Haversian systems emanating from the posteromedial cortex. The anterior cortex was only 20% of the width of the posteromedial cortex. Because of the marked thickening of the posterior cortex, the central medullary canal of the bone was displaced anteriorly (Fig 8). Examination of the tibial bone using polarized light showed that the types of bone differed from region to region (Fig 9). The radiating bone posteriorly and the extreme apex of bone anteriorly were predominantly of the more immature woven variety, though about 20% of the total bone was lamellar. The lamellar bone was seen about the perimeter of the woven bone scaffold. The remainder of the diaphyseal cortical bone was well-formed lamellar. The bone of the metaphyses and subepiphyseal new bone were predominantly woven. These findings imply that bone formation and/or turnover was greatest in the region of the "bend,"

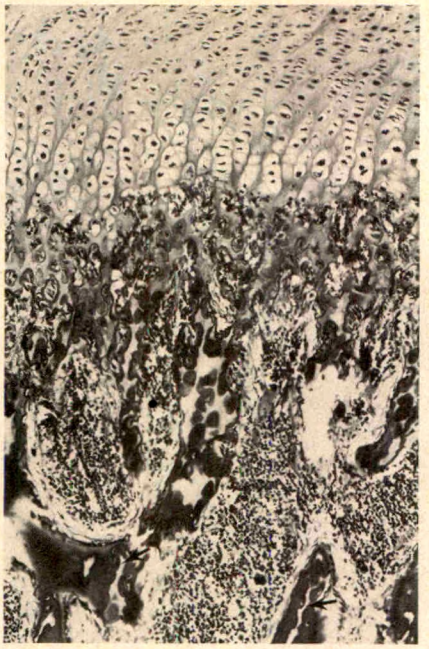

Fig 6.—Photomicrograph of tibial epiphysial plate with columnation. Though degree of columnation may be diminished somewhat, overall configuration of cartilage cells and organization is in sharp distinction to prominent disorganization and lack of columnation seen in achondroplasia. Subepiphyseal bony trabeculae are forming normally and contain central, necrotic cartilage cores (arrows), which represent normal primary spongiosa of infancy (hematoxylin-eosin, ×125).

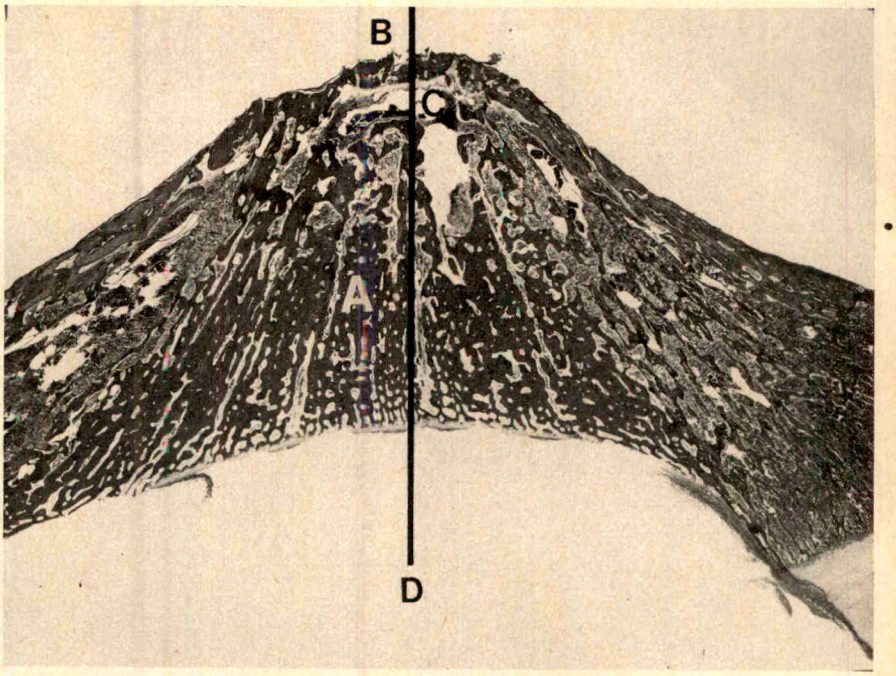

Fig 7.—Low-power photomicrograph of longitudinal section of midshaft of right tibia. Note prominent, centrally radiating spicules of thick trabecular bone (A) that arise from posterior cortex. This bone has no central cartilage cores and presumably arises by appositional growth from periosteum. Note also thin anterior cortical bone (B) over apex of curvature. Anterior portion of bone is more curved than posterior. Central nutritive vessel is displaced anteriorly and eccentrically (C). Metaphyseal areas (extreme right and left of field) do not appear abnormal (hematoxylin-eosin, ×6).

the metaphyseal cortex, and beneath the epiphyseal plate. Though woven bone is to be expected in a child this age in the metaphyses and subepiphyses, the presence of considerable quantities of woven bone at the midshaft bend is abnormal and consistent with abnormal stress to this region. The degree of mineralization of the entire bone appeared normal. The collagen pattern by polarized light examination appeared to be within normal limits, considering the patient's prematurity, except for the region of the bend (Fig 9) and did not resemble the markedly diffuse, woven-bone collagen abnormalities seen in patients with osteogenesis imperfecta in this age group.

Sections of the femora at the sites of their bowing showed changes similar to those described for the tibia. The humeri were not grossly bowed. However, cross section of the midshaft of the right humerus revealed thickening of the anteromedial cortex with evidence of subperiosteal new bone growth. The radii and ulnae were also straight on gross inspection. However, cross section of the diaphysis of the right radius revealed thickening of the anterior cortex with evidence of subperiosteal new bone growth. Mineralization of the bones of the arms and forearms was normal. The bones of the middle finger of the right hand showed no abnormalities of enchondral ossification. The proximal phalanx was normal in length (12 mm), but the middle phalanx was slightly short (6.5 mm in length), and the distal phalanx was hypoplastic (only 1.5 mm in length). Multiple sections through the pelvis revealed no histologic abnormalities of bone and cartilage at this site except for deficiencies in the formation of secondary ossification centers. The lumbar vertebrae appeared normal. The fourth lumbar vertebra measured 6.5 mm in height. The costochondral junction was histologically unremarkable.

COMMENT

Based on the clinical, radiologic, and pathologic findings presented, it is clear that our case falls within the subgroup of campomelic patients that Khajavi et al[3] termed the long-bone or classic type of campomelic syndrome. The relatively long and slender nature of the tubular bones with smooth, nonflared metaphyses and the vertical ischia are important distinguishing features in this regard.

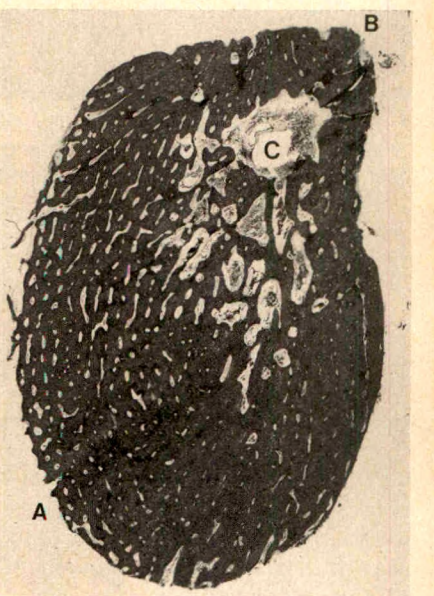

Fig 8.—Low-power photomicrograph of cross section taken through center of tibia (corresponds to line D of Fig 7). Markedly thickened areas of cortex correspond to posteromedial portions of bone (A) and thinner, more normal cortical thicknesses correspond to anterolateral regions (B). Note also anterolaterally displaced marrow cavity with central nutritive vessel (C). (hematoxylin-eosin, ×15).

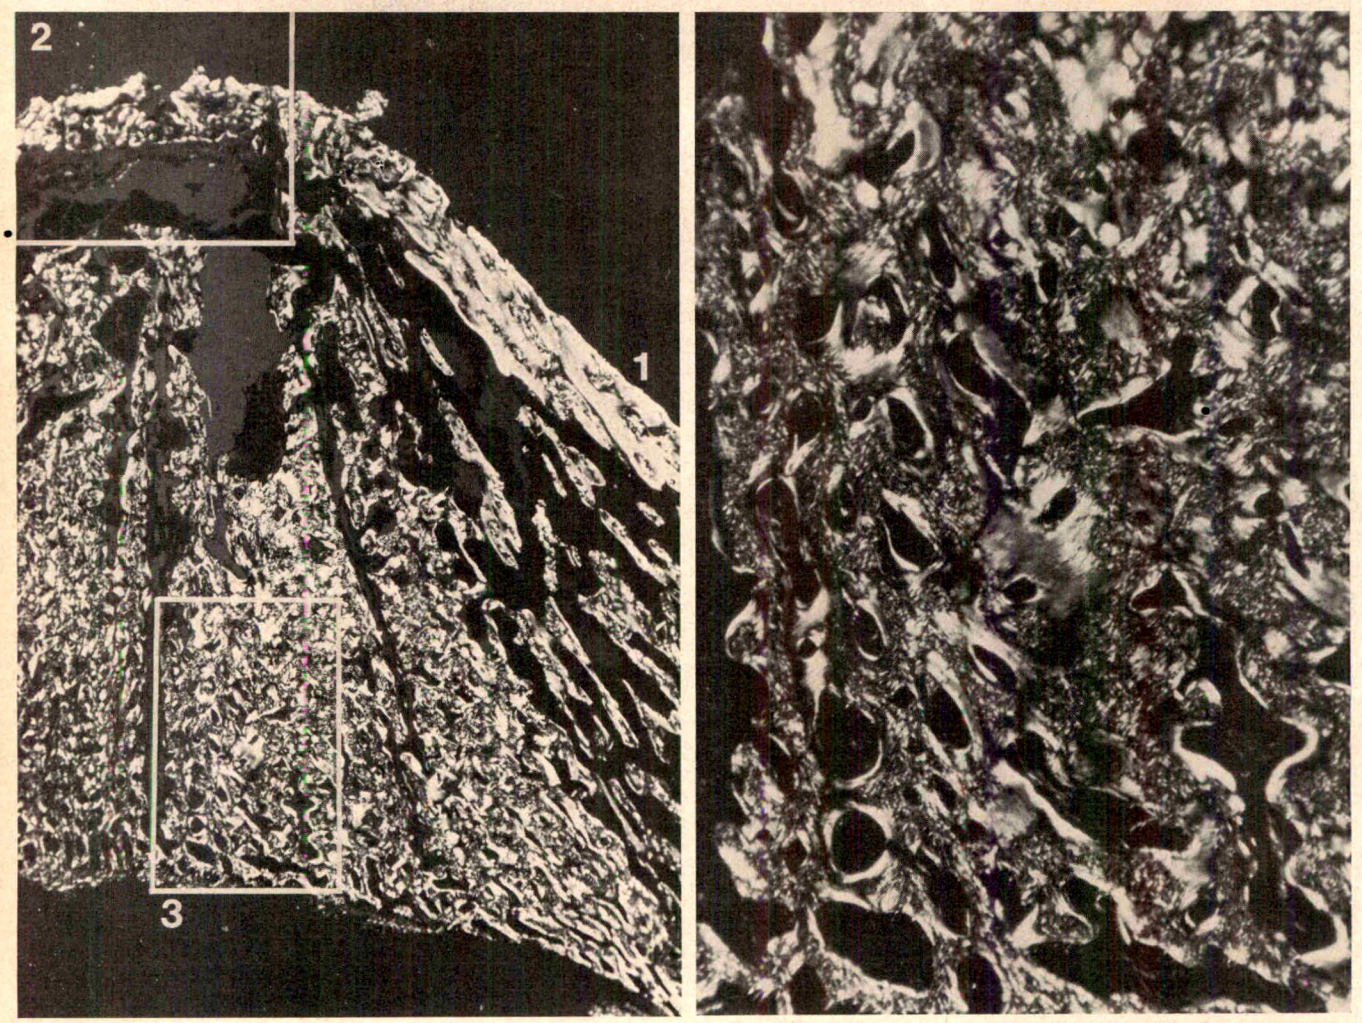

Fig 9.—Photomicrographs of midshaft of tibia under polarized light. Left, Low power showing predominant woven bone pattern along curvature of tibia (insets 2 and 3). Shaft away from area of maximal curvature (1) shows pure lamellar bone pattern (hematoxylin-eosin, ×10). Right, Higher-power view of representative area of thick posterior cortical bone region of bend (inset 3) showing predominantly woven bone with thin covering of brighter, well-oriented lamellar bone (hematoxylin-eosin, ×40).

Bone Abnormalities

Our review of the previously reported cases of the campomelic syndrome has indicated 38 cases[1-20,25,26] (18 of them autopsied) that appear to meet the skeletal criteria for long-limbed campomelic dwarfism. There has been considerable controversy about the nature of the bone abnormalities in long-limbed campomelia. Of the 15 cases prior to our own in which bone histology was reported, eight[1,3,11,16] showed changes similar to those we have described. We interpret those changes as secondary effects and not indicative of a primary abnormality of bone growth. The other seven cases[2,7,17,20,26] were said to show defects in cartilage growth and other abnormalities. To determine whether or not this indicated a heterogeneity in the bone pathology of long-limbed campomelic dwarfism, we have reviewed the available evidence from these cases. Bain and Barrett[7] described acellular cartilaginous cores in some bony trabeculae of the tibia. Our case showed similar bone enveloping dead cores within the metaphysis. It was normal in amount and location and merely represented the normal primary spongiosa of developing infants; it was not evidence of an abnormality of cartilaginous growth as stated in their communication. Lee et al[2] described defects of cartilage proliferation in their cases 1 and 3. The changes in regularity and length of the columns of the cartilage at the epiphyses in case 3 appear minimal to us. In the absence of an age-matched control subject, it is difficult to determine the severity of the irregularity and shortening of the columns of cartilage in their case 1, but the pictures presented do not indicate to us a serious or primary alteration in epiphyseal cartilage growth and maturation. Minor changes, if present, may well be secondary to a more generalized disturbance of uncertain nature.

Case 1 of Hovmoller et al[17] is also supposed to show reduced height of the proliferating and hypertrophic zones of the epiphyseal cartilage, but the example presented in the only

photograph looks essentially normal. Those authors also claimed that the posterior part of the tibial shaft at the site of the bend showed morphologic evidence of low turnover rates. By contrast, histologic examination of our case in normal and in polarized light indicates higher rather than lower turnover in the posterior tibial shaft, as evidenced by the presence of substantial amounts of primitive woven bone, when compared with the normal lamellar bone seen in the diaphyseal cortex away from the region of radiating spicules. Normally, the center of the diaphysis of a newborn is the most lamellar portion of the bone. We interpret the case of Hovmoller et al as showing histology essentially similar to that of our case except for the presence of brown pigment in the intercellular matrix, which they alone have described.

Thurmon and Kityakara[26] described "defective endochondral ossification" in their case 3. Like Bain and Barrett,[7] they described persistence of cartilage within bony trabeculae, which we interpret as the normal primary spongiosa of newborns and infants. We also disagree with their suggestion that a defect in osteoclasts may be responsible for the observed effects. They mentioned that the osteoclast is rich in alkaline phosphatase. Actually, the osteoclast is rich in acid phosphatase and contains no alkaline phosphatase. A defect in osteoclasts should lead to osteopetrosis; campomelic dwarfism bears no resemblance to osteopetrosis. If they meant that there was evidence of an osteoblastic disorder, neither did we encounter evidence to support this suggestion. Mineralization appeared normal on x-ray films, and the strength of the bones appeared normal on gross examination and on sectioning. Good lamellar bone was forming in areas. The two cases of Krous et al[20] are described as showing mild to moderate shortening and some irregularity of cartilage columns at the epiphyses of long bones, but these again lacked age-matched control subjects.

In summary, we find no convincing evidence in our case or in the literature for notable heterogeneity in the pathology of the long bones in this form of campomelic dwarfism. Furthermore, we find no evidence for a defect either in bone collagen, ground substance, or mineralization.

However, in analyzing the in vivo and specimen roentgenograms and the histology of our case in the light of Wolff's law (which states that bone is laid down along lines of compressive or tensile stresses), there is evidence of excessive compressive forces posteriorly in the long bones. This is most severe in the tibia and femur and results in radiating trabeculae of periosteal new bone laid down to resist the stress. The anterior portion of the bend shows a thin cortex that is rich in woven bone consistent with an excess in tensile stress. Such increased stress must be relayed to the bone by the much larger posterior (as compared with the anterior) muscle groups in the thigh and upper leg. Surprisingly, we found, as did Middleton,[4] that the muscles of the extremities are anatomically normal in size and contour. Furthermore, except for the case of Schmickel et al,[12] which was said to show focal atrophy of the gastrocnemius muscle, neither we nor others have detected histologic abnormalities of muscle in campomelic patients.

Nonetheless, the observation that the bones show normal radiologic density and appear to have normal gross breaking and cutting strength, while the osteoblasts appear to have the capacity to form lamellar bone without woven bone in some cortical areas, suggests that the basic abnormality may be increased muscle stress. It is almost as if the long bones were forming normally for a period during embryonic or fetal development, and then at some later stage a change occurred in the muscles (such as shortening or contraction by an unknown mechanism). This effect would be most disproportionate in the larger, dominant muscle groups of the thigh and upper leg. As a result of greater posterior stress on it, the bone would respond by the production of massive posterior periosteal new bone formation and remodeling. The central anterior bowing would result from remodeling to conform to the disproportionate stress applied posteriorly. The frequent finding of equinus deformities of the feet in campomelic patients provides support for such a hypothesis. Also, the presence of anatomic abnormalities of the nervous system accompanied by generalized muscular hypotonia at birth in these infants makes a defect in the tonus of antagonistic muscle groups during development at least plausible. It seems clear that the bowing, which may involve all four extremities, is far too consistent in direction to be merely the result of a chance abnormality of fetal position. The proposed hypothesis of early muscular imbalance might be tested by (1) prompt evaluation of fetal campomelic dwarfism detected through prenatal diagnostic studies and (2) electromyographic studies on cases recognized at birth.

The pathogenesis of the bony abnormalities of the skull and trunk is even more mysterious. However, here again the available evidence suggests no primary abnormality of bone matrix formation or mineralization. The large skull is probably secondary to the large brain size of many of these infants. Vertebral, pelvic, and scapular abnormalities might also be explained by imbalances of muscle tonus similar to those invoked to explain the bending of the long bones.

Extraskeletal Abnormalities

A comparison of the extraskeletal manifestations of our case of campomelia with those in previously reported cases (Table 2) shows both the multisystem involvement and the considerable heterogeneity of findings within the syndrome. Among the most frequent abnormalities are foot deformities and cleft palate. Abnormalities of cartilage involving the ears, tracheal and laryngeal cartilages, and epiglottis are present in about half of reported cases, leading some authors to suggest a generalized defect of cartilage maturation. However, it appears clear that abnormalities of tracheal or laryngeal cartilages do not totally account for the respiratory distress experienced by these patients, since respiratory distress has been a universal feature of the condition in patients with normal as

well as abnormal tracheobronchial trees. The generalized nature of this disorder is further shown by the frequent occurrence of cardiac, renal, and CNS abnormalities. Newborns with campomelia are almost uniformly hypotonic, which may contribute to their respiratory difficulties. Though it is tempting to try to relate the bowing of the long bones to some neuromuscular dysfunction (as aforementioned), no single anatomic abnormality of the CNS has been detected in more than a few cases. It seems likely, however, that many of the autopsied cases did not receive a detailed examination of the brain.

Gonadal Dysgenesis

The reported association of XY gonadal dysgenesis with campomelia is a very interesting one. Of the 39 reported cases, including our own, the sex of the patients is indicated in 35. Nine of these were phenotypically male. Only three males, including our case, have been karyotyped and they show the normal male XY chromosome constitution. Of the 26 phenotypic females, 11 have been karyotyped. Seven of these had an XX sex chromosome complement, whereas four were XY. In addition, we have recently encountered at UCLA twins with campomelia, both of whom were phenotypically female but had 46,XY karyotypes. A possible case of campomelia described by Hovmoller et al,[17] which showed only unilateral tibial bowing, was also a phenotypic female with an XY karyotype. Pathologic examination of the gonads was carried out on four phenotypic males, all of whom showed normal male genitalia, and on 13 phenotypic females. Five XX females and four females who were not karyotyped showed normal ovaries. Of the four XY females examined at autopsy, one had histologically normal-appearing ovaries with occasional, undifferentiated germ cells but no primordial follicles, one had testes, and a third had poorly differentiated ovaries containing some germ cells that were in meiotic prophase as would be expected of XX germ cells. The fourth case showed grossly normal ovaries, as did the possible case of Hovmoller et al,[17] but histologic examination was not performed. Thus, it appears that a subgroup of female campomelic patients have XY gonadal dysgenesis, but that the majority of females with this disease are genotypically XX. From the brief description of the findings in cases of campomelia with gonadal dysgenesis, it does not appear that these patients differ from others in their skeletal abnormalities or in their pattern of associated extragonadal abnormalities.

The etiology of campomelic dwarfism remains unclear. Any theory that would explain the syndrome must take into account the wide spectrum of abnormalities involving many organ systems. The occasional occurrence of the disease in siblings (with the mother showing some stigmata of the disorder in one instance[13]) and the presence of parental consanguinity in another case suggest that a subgroup of the cases may have a genetic abnormality. The finding of a proliferative placental villitis in their case led Krous et al[20] to postulate a viral etiology. It is possible that a variety of noxious agents acting at a susceptible time during gestation is capable of producing this syndrome. In several cases, a variety of drugs had been taken by the mothers of these infants during gestation but these agents were not proven teratogens.

Though much has been learned about this fascinating syndrome, it is obvious that to completely elucidate the basic mechanisms responsible for the morphologic features and symptoms of this disease, further studies are needed. Quantitative analyses of bone strength, mineral and collagen content of bone, muscle histochemistry, and extensive neuromuscular examination of these patients should be performed in future cases of this syndrome.

Nosocomial Scalded Skin Syndrome

Ritter's Disease Caused by Phage Group 3 *Staphylococcus aureus*

Alfred L. Florman, MD, Robert S. Holzman, MD

• **Three cases of generalized exfoliative staphylococcal scalded skin syndrome (SSSS) were encountered during a 25-day period in a nursery for premature infants. A single strain of *Staphylococcus aureus*, phage type 42E/54/75 (group 3), was recovered from each of the three infants and from no others. Two of the three isolates were tested and both produced epidermolytic toxin (ET). Most cases of SSSS have been associated with phage group 2 strains. To our knowledge, this is the first report of a nursery outbreak caused by a phage group 3 staphylococcus. It illustrates that ET production and not phage type distinguishes *S aureus* strains that are associated with SSSS.**

(*Am J Dis Child* 134:1043-1045, 1980)

Staphylococcal scalded skin syndrome (SSSS) has been well described. Despite some superficial similarities and earlier confusion, it now has been differentiated clinically and histologically from drug-induced toxic epidermal necrolysis.[1-3] In 1971, it was suggested by Melish and Glasgow[4] that SSSS be considered a spectrum of rashes that includes a generalized exfoliative disease in infants (Ritter's disease), a generalized scarlatiniform erythema without exfoliation, and bullous impetigo. This was because all of them are caused by an epidermolytic toxin (ET), which up to that time had been exclusively associated with phage group 2 strains of *Staphylococcus aureus*. However, a report from Japan[5] now states that only four of 21 children with SSSS seen during a four-year period had phage group 2 isolates. All others had strains in either phage group 3 or both 3 and 1. We report the first nursery outbreak of the generalized exfoliative form of SSSS (Ritter's disease) associated with a phage group 3 *S aureus*.

REPORT OF CASES

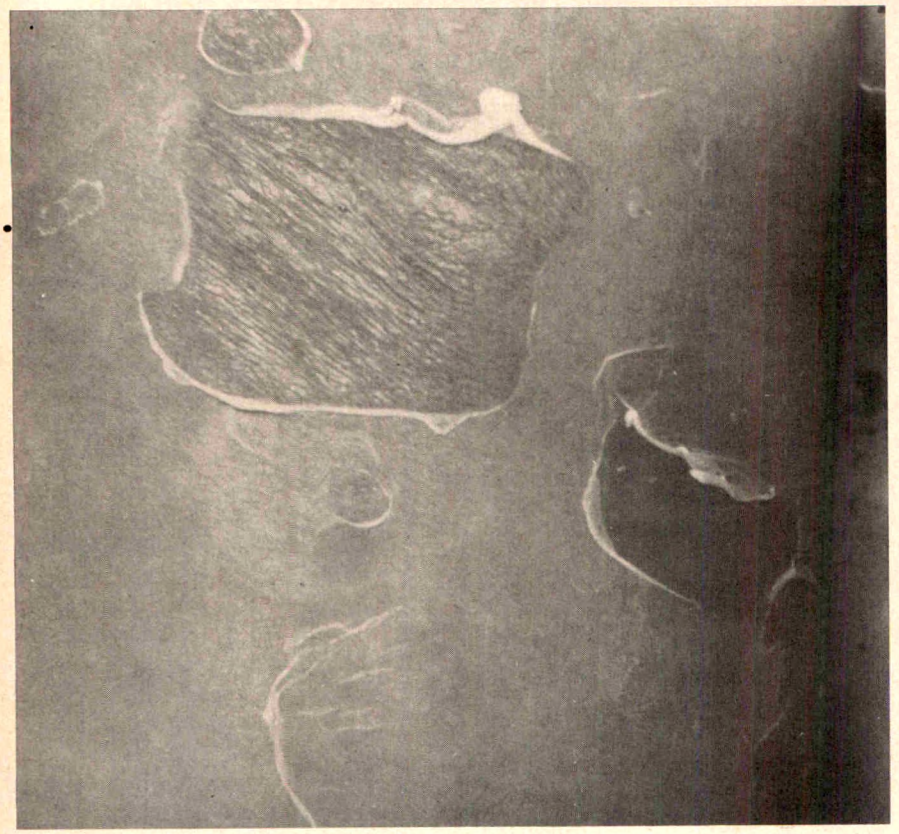
Case 1.—A female infant was born prematurely on March 12, 1979, weighing 2.1 kg. She was cared for in a five-bassinet room (R40) of a six-room special care nursery (SCN), and remained well until 17 days of age, when an erythematous rash was noted first in the perioral area. It quickly spread to involve the entire body. Blisters and desquamation appeared about the mouth, upper eyelids, axillae, vagina, and over the trunk (Fig 1). Despite this, she remained afebrile, alert, and vigorous. The WBC count was 10,900/cu mm, with 46% neutrophils, 13% band forms, 30% lymphocytes, and 5% eosinophils. She was moved from the SCN, placed in isolation, and treated with parenteral oxacillin sodium for ten days. One week later, the skin was clear except for some residual peeling on the hands and feet.

Case 2.—A male infant was born prematurely on March 29, 1979, weighing 2 kg. After 30 hours of care in the intensive care unit (ICU), he was transferred to R40, arriving there 24 hours after patient 1 had left. Because of respiratory distress, he was treated with ampicillin sodium and gentamicin sulfate for the first five days of life. On the 16th day of life, a red rash was noted about the mouth. The rash spread quickly to cover his entire body, and vesicles appeared in the groin. The next day, there was peeling about the mouth. He remained afebrile. His WBC count was 10,500/cu mm, with 29% neutrophils, 17% band forms, 53% lymphocytes, and 1% eosinophils. He was transferred out of the unit, placed in isolation, and treated with parenteral oxacillin and kanamycin sulfate for five days. By that time, the rash had cleared completely.

Case 3.—A male infant was born March 30, 1979, by cesarean section, weighing 1.4 kg. At 5 days of age, he was transferred from the ICU to R40. At 26 days of age, a circumoral rash was noted. The next day, peeling appeared about the eyes and groin. He was afebrile. His WBC count was 7,700/cu mm, with 13% neutrophils, 6% band forms, 71% lymphocytes, 6% monocytes, and 4% eosinophils. He was moved out of the SCN, placed in isolation, and treated with parenteral oxacillin for ten days, with rapid improvement. He had been in R40 with patient 2 for 11 days before that child experienced his rash.

BACTERIOLOGIC FINDINGS

Staphylococcus aureus was recovered from the nose of each of the three



Appearance of rash of patient 1 after 24 hours.

infants. Blood cultures from all three were negative. Isolates were shown to be a single strain both by antibiogram and phage type. They were resistant by disk testing to penicillin, streptomycin, and tetracycline (except that the isolate from patient 3 was sensitive to tetracycline), and all were sensitive to oxacillin, erythromycin, and gentamicin. Isolates from all three infants and from a physician carrier were phage typed using both the international basic set of phages and a number of experimental phages. The staphylococci were phage type 42E/54/75. These phages are in group 3 of the international set. With the New York City Department of Health set of experimental phages, they all were typed as 1141/1135/1127/1049/1976/1136.

TOXIN PRODUCTION

Isolates of the epidemic strain from patients 1 and 2 and from a physician carrier were tested using a suckling mouse assay.[6] All three isolates were shown to produce an ET.

EPIDEMIOLOGIC FINDINGS

It has been the practice to take weekly surveillance cultures for *S aureus* from the anterior nares of all infants in the ICU and SCN. After the first case was diagnosed in the SCN, nose cultures were also obtained from 28 members of the nursing and medical staffs. Although eight had cultures that were positive for *S aureus*, only one isolate, from a house officer, showed the same antibiogram and phage type as the patient. It was impossible to determine if the physician had introduced the organism to the SCN or had acquired it there. However, she left the service 12 days before case 2 was recognized. After the second case, nose cultures were obtained from 26 members of the staff then assigned to the unit. None were found to have the epidemic strain. A review of all surveillance cultures taken in both ICU and SCN from two weeks before the appearance of the first case until two weeks after the third failed to reveal any other infants with this strain. Relatively few environmental cultures were taken. However, on the same day that a surveillance culture from case 2 was found to be positive, the hyperalimentation fluid being given to another infant in that room was also reported as positive for *S aureus*. This culture was obtained prior to passage of the fluid through an in-line filter. Because all cases occurred in the same room (R40), an environmental source was suspected. Consistent with this suspicion, no further cases occurred after R40 was closed to new admissions and all infants in the unit were given a single bath with 3% hexachlorophene. The room was reopened only after the cohort of babies had all been discharged.

COMMENT

In 1878, Ritter described what he called "dermatitis exfoliativa neonatorum" among young infants in a foundling hospital in Prague. Today, this would be recognized as generalized SSSS in neonates. Ritter considered the disease noninfectious.[2] In retrospect, many of his cases must have been nosocomial infections. An association with *S aureus* became clear by the early 1900s.[2] When phage typing became available in the early 1960s, it seemed that only staphylococci in phage group 2 were involved.[7]

In 1952, Lee et al[8] reported what they believed to be the first nosocomial epidemic of Ritter's disease in a nursery in the United States. On the basis of clinical and autopsy findings, they suggested that a staphylococcal toxin might be the cause. It was not until 1970 that Melish and Glasgow,[6] with the use of a suckling mouse model, were able to show that this indeed was so and to partially purify the toxin obtained from phage group 2 isolates. Although group 2 strains have continued to predominate, occasionally non-group 2 strains were recovered from patients in the United States.[9] In Japan, there has been a recent shift to such strains.[5] In 1974, Kondo et al[10] described an ET from non-group 2 strains that elicited the same reaction in suckling mice as did the toxin from group 2 strains. However, it differed serologically and was

more sensitive to heat. They called the toxin obtained earlier from phage group 2 staphylococci "exfoliatin A" and the one from the non-group 2 strains "exfoliatin B." Subsequently, they found that production of ET serotypes (A or B) was not restricted to specific phage types.[11]

At about the same time, Rogolsky et al[12] presented evidence that the gene for production of ET from a phage group 2 strain was located in a plasmid. Since plasmids may be lost easily or transferred, such dissociation of ET production and phage type is not surprising. The phage group 3 strain of *S aureus* isolated from our patients produced ET when it was tested in suckling mice. We do not know whether the toxin was serotype A or B.

In 1976, Faden et al[13] reported a nursery outbreak of SSSS with a scarlatiniform rash caused by an ET from a phage group 1 *S aureus*. That report, together with our experience and that from Japan,[5] serves to illustrate that ET production can occur with phage group 1 and 3 as well as group 2 staphylococci. It is ET production and not phage type that distinguishes *S aureus* strains associated with SSSS. In a susceptible host, this syndrome may be caused by ET producing staphylococci from any of the phage groups.

Samuel Schaefler, PhD, New York City Department of Health, performed the phage typing. Lowell A. Glasgow, MD, Utah College of Medicine, Salt Lake City, tested the isolates of the epidemic strain for ET production.

60 YEARS AGO IN THE AJDC

Pneumococcus Peritonitis in Infancy and Early Childhood

Reports of this disorder were the subject of six prior works dating from 1902 so that the entity was not new to observers. In thirteen years of experience at the Babies Hospital of New York, general peritonitis had been seen in 171 cases. Of these, nine had been demonstrated by culture to be due to the pneumococcus. Patients' ages ranged from 9 months to 4 years, the younger ages being more common because of the young age of the inpatient population.

Of the nine children, seven had a clearly demonstrated focus in the lung which antedated the development of peritoneal signs by as long as a month. There was fever in all; many had palpable abdominal masses and abdominal swelling. In one there was associated meningitis. The leukocyte count was elevated modestly with a prominence of polymorphonuclear forms. In two, the leukocyte count was over 25,000. In this group there was a single survivor.

In two children aged 2 and 2½, the mode of onset differed. There was high fever, vomiting, abdominal pain, and in one, diarrhea. No antecedent respiratory infections or symptoms had occurred. Both children were toxic, with tender and distended abdomens. In one leukopenia was noted; the leukocyte count in the other was 38,000 with 88 per cent. polymorphonuclear forms. One child had an exploratory laparotomy with findings of generalized peritonitis. Death ensued in both.

The pathogenesis of this condition has been debated. Some authorities feel the pneumococcus enters through the ear, others suspect the intestinal wall. The author agrees with most that this infection enters through the lung and that in certain cases the lung does not show any clear focus at all.

The treatment advised for penumococcal peritonitis is to keep the patient fully under the influence of morphia to keep the intestines at rest. Once localization of an abscess occurs, surgical drainage can be undertaken.—Paul W. Bearan, MD, Babies Hospital, New York (20:341-346, October 1920).

Cutaneous Necrosis Associated With Intravenous Nafcillin Therapy

Samuel J. Tilden, MD; J. Carl Craft, MD; Roberto Cano, MD; Robert S. Daum, MD, CM

• **Four children had cutaneous necrosis associated with the administration of intravenous (IV) nafcillin sodium therapy. One patient required skin grafting. Hospitalization was prolonged with this patient and with one other in an effort to ensure healing. Adult rats, inoculated subcutaneously with nafcillin that was appropriately diluted according to manufacturer's recommendations, exhibited similar lesions. Oxacillin sodium, methicillin sodium, and cephalothin sodium, similarly diluted, did not necrose skin. Nafcillin should be added to the list of agents that produce similar toxic conditions. Frequent observation of the IV infusion site to detect extravasation may obviate this hazard.**

(*Am J Dis Child* 134:1046-1048, 1980)

Nafcillin sodium is a semisynthetic, penicillinase-resistant penicillin, similar to oxacillin sodium and methicillin sodium in its antimicrobial spectrum. Intravenous (IV) therapy with nafcillin has been associated with several adverse reactions, including neutropenia, fever, rash, thrombophlebitis, and possibly nephropathy.[1-4] We have observed four patients with severe skin slough during IV nafcillin therapy; the purpose of this report is to alert clinicians to this hazard.

REPORT OF CASES

CASE 1.—A 4-month-old female infant was admitted to Charity Hospital, New Orleans, in September 1978 for periorbital cellulitis. Initial therapy included IV nafcillin sodium (Unipen) at 150 mg/kg/day and chloramphenicol (Chloromycetin) sodium succinate at 80 mg/kg/day, each divided into four daily doses administered through a butterfly needle placed in a vein on the dorsum of the left hand. Nafcillin was administered intravenously over a period of 15 minutes after having been diluted in approximately 15 mL of 5% dextrose in water (final concentration, nafcillin sodium, 17.5 mg/mL diluent). Immediately after infusion, infiltration was observed; a small, nonerythematous, nontender vesicle surrounded the site. In the next six hours, this lesion progressed to a 3 × 1-cm area of discoloration. Progression to frank dermal necrosis with epidermal sloughing gradually developed over a four-day period. Treatment with sterile saline compress and application of sulfadiazine silver four times daily resulted in regression of the lesion, which was granulating well at the time of discharge from hospital on the 12th day. Nafcillin therapy was discontinued on the second hospital day after *Haemophilus influenzae* type B was grown in cultures of blood.

CASE 2.—A 9-day-old male infant was admitted to hospital in October 1978 for bullous impetigo. Aspiration of fluid from a bullous lesion revealed Gram-positive cocci with subsequent isolation of *Staphylococcus aureus*.

Initial therapy included IV nafcillin sodium at 200 mg/kg/day in four doses, which was administered in approximately 15 mL of 5% dextrose in water (final concentration, nafcillin sodium, 7 mg/mL diluent) via a butterfly needle placed in a scalp vein. On the sixth day of therapy, subcutaneous extravasation was noted after nafcillin infusion. Twenty-four hours later, the area of infiltration spread to involve a 5 × 5-cm area over the right frontoparietal region. This lesion was at first erythematous, became dusky, and showed frank necrosis at 48 hours. This process was severe, with bone visible in the depth of the wound (Fig 1). A right temporal transposition flap with split-thickness skin graft was required to cover the defect after debridement, and the patient was discharged without further complications on the 30th hospital day.

CASE 3.—A 7-week-old male infant was transferred to Tulane University Medical Center, New Orleans, for evaluation of facial cellulitis, bilateral otitis media, bilateral periorbital cellulitis, and a perforated nasal septum.

Initial antimicrobial therapy included IV nafcillin sodium (200 mg/kg/day in four doses) and gentamicin sulfate (7.5 mg/kg/day divided into three doses); slow resolution of the infected areas was noted. However, cellulitis over the nose and superior maxillary area persisted, and IV therapy was continued. On the 16th day, the IV solution (delivered from a 25-gauge butterfly needle) infiltrated into the dorsum of the right foot 1½ hours after nafcillin administration (in 15 mL of 5% dextrose

Fig 1.—Right frontoparietal cutaneous necrosis observed 24 hours after intravenous nafcillin sodium therapy. Patient required skin grafting (case 2).

in water; final concentration, nafcillin sodium, 10 mg/mL diluent). Over 48 hours, the skin became dusky, blue, and necrotic and sloughed over a 4 × 2-cm area; satellite blisters were present at the perimeter. Sulfadiazine silver cream was applied topically, and the patient was discharged one week later with the wound granulating well.

CASE 4.—A 3-month-old female infant was admitted to hospital for evaluation of congestive heart failure and pneumonia. Therapy included IV nafcillin sodium (200 mg/kg/day in four doses) and gentamicin sulfate (5 mg/kg/day in three doses). During transit to Charity Hospital, a dose of reconstituted nafcillin sodium (250 mg/mL) was given intravenously over a five-minute period via a 22-gauge IV catheter in the right antecubital fossa. No other medication was given in transit. On arrival, examination of the extremities revealed a 22-gauge catheter in the right antecubital vein surrounded by a 1.5-cm bulla.

The patient was treated for congestive heart failure, and the IV infusion site was changed. Bacitracin ointment was applied to the blistered area. However, no improvement was noted in the skin lesion ten days later when the infant died after cardiac surgery.

ANIMAL STUDIES

Adult Sprague-Dawley outbred albino rats were inoculated with nafcillin, oxacillin, methicillin, cephalothin sodium, or 5% dextrose in water. All antimicrobial solutions were freshly prepared by reconstitution with sterile water or 5% dextrose in water according to the manufacturer's recommendation. Further dilution in 5% dextrose in water yielded solutions appropriate for direct IV instillation (Table). The hair over the abdomen was trimmed with an electric shaver, and 0.2 mL of a test solution was inoculated subcutaneously. The skin over the inoculation site was inspected by a blinded observer 2, 12, 24, 48, and 96 hours after inoculation; all solutions were evaluated in duplicate.

RESULTS

The results are summarized in the Table. Undiluted methicillin and nafcillin produced severe necrosis 24 hours after inoculation. Necrosis with high-concentration oxacillin was less severe; cephalothin did not necrose the overlying skin. When diluted to concentrations recommended by manufacturers for IV infusion,[5] only nafcillin produced necrosis (Fig 2). No skin changes were observed after inoculation with 5% dextrose in water.

COMMENT

Intravenous nafcillin therapy has been associated with minimally toxic conditions in pediatric patients. Feldman et al[6] reported phlebitis in one of 46 patients, transient neutropenia in two of 30, and mild elevation of SGOT levels in three of 27 patients treated with nafcillin for presumed or proven staphylococcal infection. Arbeter et al,[3] in a double-blind comparison of nafcillin and oxacillin therapy, observed thrombophlebitis in 17 of 52 patients who were receiving nafcillin; 14 of 17 were 10 years of age or older. By contrast, thrombophlebitis developed in only four of 62 patients who were treated with oxacillin. Elevated SGPT concentrations occurred in 13 of 62 patients receiving oxacillin and in six of 52 patients receiving nafcillin.

We observed four infants, aged 9 days to 4 months, who had cutaneous necrosis associated with the administration of IV nafcillin. The technique of nafcillin administration was reviewed with the appropriate nursing personnel; in each case, patency of the IV line was established prior to nafcillin administration. As per the manufacturer's recommendation,[5] nafcillin sodium was first reconstituted to a concentration of 250 mg/mL with sterile water. With the exception of patient 4, it was next diluted in 15 to 20 mL of 5% dextrose in water and administered over a period of 15 to 30

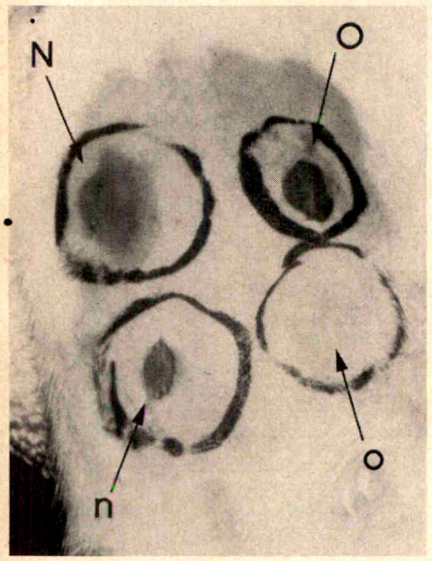

Fig 2.—Cutaneous necrosis after subcutaneous injection of 0.2 mL of nafcillin sodium or oxacillin sodium. N indicates nafcillin sodium, 250 mg/mL; n, nafcillin sodium, 40 mg/mL; O, oxacillin sodium, 167 mg/mL; o, oxacillin sodium, 40 mg/mL.

minutes. At least two different lots of nafcillin were used in our patients. Treatment of the necrotic area consisted of local care except in one patient who required skin grafting; in two patients, hospitalization was prolonged because of the severity of their lesions.

Other agents have been associated with cutaneous necrosis after IV extravasation. Doxorubicin, mechlorethamine hydrochloride, mitomycin, vincristine, calcium salts, norepinephrine, sodium bicarbonate, radiopaque contrast material, methylene blue, and 10% dextrose in water have all been implicated in this regard.[7-12] None of the aforementioned agents were administered to any of our patients.

Experimental subcutaneous inoculation of adult rats with nafcillin produced lesions similar to those observed in our patients. Dermal necrosis was not observed after methicillin, oxacillin, and cephalothin inoculation.

Since the occurrence of these cases, we have emphasized the importance of careful dilution of nafcillin prior to administration and frequent observation of the IV infusion site, with prompt discontinuation of therapy if any suggestion of infiltration is present. These precautions may help to minimize cutaneous necrosis but may not be fully preventive. Physicians who choose IV nafcillin therapy for their patients should be aware of cutaneous necrosis as a hazardous complication of therapy.

Wesley Galen, MD, reviewed the manuscript. John Willard and Barbara Palmisano, MD, assisted with the rat experiments. Kathleen Kustudich provided secretarial support.

Early Growth Patterns of Methadone-Addicted Infants

Ira J. Chasnoff, MD; Roger Hatcher, PhD; William J. Burns, PhD

• **The early growth patterns of 15 full-term infants born to mothers on well-controlled, low-dose methadone hydrochloride maintenance were studied. Mean birth weight and length were at the tenth percentile, and mean head circumference was at the fifth percentile. Early withdrawal symptoms persisted for three to four months, and mean growth parameters continued along their respective percentiles. As withdrawal symptoms abated at 4 to 6 months, infants became more responsive, easier to handle, and demonstrated an accelerated growth pattern. This acceleration of growth at 4 to 6 months of age corresponded to patterns found in previous animal studies.**

(*Am J Dis Child* 134:1049-1051, 1980)

Though the literature has had very little information on the methadone hydrochloride-addicted neonate, there now is evidence that the early symptoms described in the neonatal addict continue in attenuated or subacute form throughout early infancy.[1-3] Restlessness, hyperactivity, brief sleep, and colic and feeding problems reportedly continue for the first two to three months. At approximately 4 to 6 months, however, the infants become more responsive and easier to handle and demonstrate catch-up developmental growth. At present, there is no longitudinal information regarding the somatic growth of methadone-addicted newborns during this period. This study reports the early growth patterns of infants born to mothers on low-dose methadone maintenance.

PATIENTS AND METHODS

Fifteen infants born during 1978 to mothers on a well-controlled, low-dose methadone maintenance program at Prentice Women's Hospital and Maternity Center, Chicago, were studied prospectively. All of the women had conceived while taking heroin and joined the methadone maintenance program in the first or early second trimester of pregnancy. Maternal urine samples were obtained daily in order to screen for illicit drug use. Intensive prenatal care was provided for each woman, and, in addition, each prospective mother received individual counseling and family therapy. Eighteen women were enrolled in the program during the one-year period. Three were disqualified because of continued use of illicit drugs or were lost to follow-up during pregnancy.

The mean age of the 15 women was 23.5 ± 4.5 years. The racial identities and socioeconomic classes of the study group closely reflected the general population of the hospital. The pregnancies were uncomplicated except for one woman with gestational diabetes and four women with a positive VDRL at delivery. One woman required a cesarean section due to cephalopelvic disproportion.

Maternal weights prior to pregnancy as reported by the women, ranged from 42.7 to 75 kg. Among the study population, seven of the women were primagravidas, and six had had more than four pregnancies. There was a history of 22 previous abortions, half of which were spontaneous. Five women did not smoke tobacco, eight smoked less than or up to one pack of cigarettes per day, and two women smoked more than one pack per day.

The initial daily dosage of methadone varied among the women, but the dosage was steadily decreased to the lowest level that would prevent craving or withdrawal in the mother. By the beginning of the third trimester, each woman was on a maintenance dose of methadone. Four women received 5 mg of methadone hydrochloride daily; three women received 10 mg daily; five women received 15 mg daily; two women received 20 mg daily; and one woman received 40 mg daily. These dosages were held at the same level for the remainder of the pregnancy. No woman was completely detoxified during pregnancy. Daily methadone dosage did not vary during labor, delivery, or in the postpartum period.

Some of the maternal variables that might affect infant birth weight, eg, race, cigarette smoking, and daily and total methadone dose, were statistically analyzed. The relationships between each of these maternal variables and neonatal birth weight was assessed by χ^2 analysis.

Infants were followed up from birth and received routine well-child care by the attending pediatrician, first at weekly, and later at monthly, appointments. Each infant was observed for signs of methadone withdrawal. Weight, crown-to-heel length, and frontooccipital head circumference were recorded at each visit. Twice-weekly observations in the home regarding mother-infant interaction, infant behavior, irritability, feeding problems, and sleep patterns were recorded by a visiting nurse.

All infants were fed a standard commercial formula with iron, and solid feedings were begun at 6 months of age. Feeding history was obtained from the mothers and documented through records of home visits made by a visiting nurse. All infants received a minimum of 120 calories/kg/day throughout the study. Mothers were questioned specifically about infant behavior, irritability, feeding problems, and sleep patterns at home. All mothers underwent continuous individual counseling as well as family therapy throughout the period of follow-up with the infants.

The conditions of 11 of the infants were evaluated with the Brazelton Neonatal Behavorial Assessment Scale.[4] Four infants were discharged prior to testing. The scale was administered in a quiet room after 2 days of age by experienced examiners who had demonstrated reliability in the use of this examination. The Bayley Scale of Development[5] was administered to 12 infants at 3 months of age and again to six of these infants at 6 months.

RESULTS

General

All 15 newborns were of singleton birth at term (38 to 42 weeks) gesta-

tion as ascertained by the criteria of Ballard et al.[6] One infant had meconium staining of the amniotic fluid at delivery. The mean Apgar score at one minute was 8.1 (SD, 0.24) with one infant having a score below 7. At five minutes, the mean Apgar score was 8.6 (SD, 0.14) with all scores being 7 or above. One infant had a second-degree hypospadias; no other congenital malformations were present. No infant born to a mother with positive VDRL during pregnancy had serologic evidence of congenital syphilis.

Psychomotor Development

All 15 infants demonstrated some degree of withdrawal symptoms beginning on the second to fourth day of life. Ten infants demonstrated mild jitteriness and irritability with no progression of symptoms. Four infants demonstrated these same symptoms but to a degree that interfered with feedings and that required therapy. One infant had a generalized seizure on the third day of life. All five infants who required therapy were treated with phenobarbital, 8 to 15 mg/kg/day, and no longer received medication by 6 weeks of age.

On evaluation of the infants' conditions with the Brazelton Newborn Assessment Scale, reflexes, muscle tone and movement, and orientation responses were found to be normal. There were 11 instances of poor habituation to light and sound stimulation; eight, of rapid build-up to crying states; nine, of irritability; nine, of insulated crying states, in which the infant was inconsolable; seven, of labile state control; and nine, of predominant fussing and crying states.

Through the age of 3 to 4 months, an infant's sleep problems, hyperactivity, irritability, and feeding difficulties were reported by parents and visiting nurses. Examination of the infants by the pediatrician through this age revealed irritable infants with hypertonia and hyperreflexia. Beginning at 3 to 4 months of age, many of the symptoms and signs began to resolve, and the infants became more responsive and easier to handle. By 6 months of age, very few, if any, behavioral problems were reported by parents and nurses.

On the Bayley Scale of Development, the means of the Mental (MDI) and Motor (PDI) Indices were in the average range when infants were 3 months of age (where the mean MDI and PDI scores for the general population were 100; SD, 16). Of 12 infants tested, the mean MDI score was 103 (SD, 11.6), and the mean PDI score was 112 (SD, 14.2). At 6 months of age, there was a downward deflection of 11 and 19 points on the MDI and PDI, respectively (SD, 6 and 14.3, respectively). However, the six-month scores were within the normal range, though near the lower limit.

Growth

The mean birth weight, 2,957 g (range 2,540 to 3,742 g; SD, 349 g), of the study infants was not significantly different from the mean birth weight (3,340 g) of the general newborn population in our hospital. Using χ^2 analysis, no statistically significant relationship was found between birth weight of the study infants and racial group or between birth weight and daily or total maternal methadone dose. Though the two largest infants were born to mothers who did not smoke, there was no significant relationship between birth weight and smoking.

The mean birth weight of the male and of the female infants was plotted on a growth chart appropriate for sex constructed by the National Center for Health Statistics.[7] These charts are based on measurements of infants in the general US population.

For simplicity, the charts in Fig 1 to 3 are adapted from graphs of male and female infants so that the normal percentiles drawn in the illustrations serve for both male and female infants. The same growth patterns resulted when the mean measurements for each sex were recorded on sex-appropriate graphs.

The mean birth weight for the methadone-addicted infants fell at the tenth percentile (Fig 1). The subsequent mean weights with SDs also were plotted on the growth chart. The mean weight remained at the tenth percentile until 4 months of age, when the mean weight of the study infants began crossing the percentiles. By 7½ months of age, the mean weight of the study infants lay near the 40th percentile.

Monthly measurements of infant length demonstrated a similar pattern (Fig 2). The initial mean length of 48.4 cm (range, 46 to 52 cm; SD, 1.6 cm) lay at the tenth percentile, and subsequent mean lengths remained at this level until 4 months of age. By 7½ months, mean length for the study infants lay between the 25th and 50th percentiles. Perhaps more importantly, the mean head circumference at birth of 32.9 cm (range, 31 to 35 cm; SD, 0.01 cm) lay at the fifth percentile (Fig 3) and followed this percentile curve until infants were 4 months old, when the mean increased to the tenth percentile. By 7½ months, the infants' mean head circumference approached the 25th percentile.

COMMENT

Early withdrawal symptoms of irritability, sleep problems, hyperactivity, feeding difficulties, and hypertonia persisted for three to six months. All infants had adequate caloric intake for growth during this time, as demonstrated by the fact that weight, length, and head circumference growth were maintained at a normal rate along the fifth to tenth percentile. As withdrawal symptoms abated at 4 to 6 months of age, infants became more responsive, easier to handle, and showed an accelerated growth pattern.

This early depression of growth could be due to the direct effect of methadone on the hypothalamic-hypophyseal axis of the newborn.[8] There are many reported effects of opiates referable to the hypothalamus,[9-11] and rapid loss of body weight has been demonstrated in adult rats chronically treated with morphine.[9]

Animal studies by Friedler and Cochin have demonstrated the direct action of maternal opiates on the growth of newborn rats.[8] Rats born to mothers who had been treated prenatally with morphine had a significant depression of body weight compared with a control population. At birth, the size and weight of the experimental and control litters were similar; however, the offspring born to the mor-

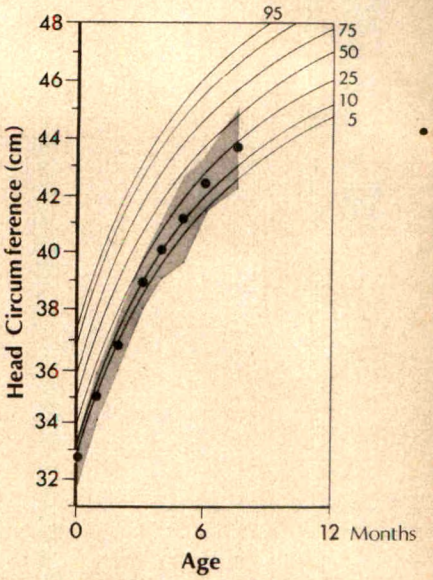

Fig 3.—Mean head circumference of study infants (N = 15) by age. Shaded area depicts ± 2 SD. For source of normal percentiles, see text.

phine-treated mothers showed a depressed rate of growth commencing at 4 weeks of age. Growth recovery then occurred, and the somatic growth of the experimental rats returned to control levels by 2 months of age.

In the newborn infant, 85% of methadone is protein bound and is converted to an active metabolite before being slowly excreted by the liver.[12] The neonatal tissues serve as a "reservoir of the drug,"[13] and the methadone exerts a persistent effect on the infant. We would postulate that, as the drug is excreted by the infant, plasma and tissue drug levels fall, the endocrinological effect of the drug subsides, and growth recovers.

Many factors influence growth, and the acceleration of growth at 4 months of age demonstrated by the infants in this study could be the result of many interacting variables, including alterations in maternal-infant interaction and nutrition. However, the data presented here do correspond to information obtained from previous animal studies and may provide valuable insight into the fundamental effects of methadone on the early growth patterns of infants born to mothers on low-dose methadone maintenance. Though the infants demonstrate an acceleration of physical growth between 4 and 6 months of age, there is no similar acceleration in their mental or motor development. In fact, there is some suggestion of a mild deceleration in psychomotor development during this period. Long-term observation and follow-up will be necessary in order to determine if these alterations in the physical and mental development of methadone-addicted infants are transitory or have more lasting implications.

This research was supported by a grant from the Illinois Dangerous Drugs Commission.

Anaerobic Bacteremia in Children

Itzhak Brook, MD, MS; Guido Controni, MS; William J. Rodriguez, MD, PhD; William J. Martin, PhD

• Twenty-nine anaerobic isolates were recovered from 28 pediatric patients with anaerobic bacteremia: 14 *Bacteroides* sp (11 in the *B fragilis* group); four anaerobic Gram-positive cocci; four *Clostridium* sp; four *Propionibacterium acnes*; and three *Fusobacterium* sp. No aerobic bacteria were isolated from these patients. The gastrointestinal tract was the possible portal of entry in 13 instances, eight of which were due to *Bacteroides* organisms, four to *Clostridium* sp, and one to *F nucleatum*. The ear, sinus, and oropharynx were probable portals of entry in seven instances, four of which were due to *Peptococcus* sp and two to *Fusobacterium* sp. Five patients (18%) died; four had bacteremia caused by *B fragilis* group, and one had bacteremia caused by *P acnes*. The average duration of antimicrobial therapy was 20 days (range, seven to 72 days). The early recognition and rapid institution of appropriate antimicrobial and surgical therapy are of utmost importance in improving the outcome of these patients.

(*Am J Dis Child* 134:1052-1056, 1980)

Anaerobic organisms have been rarely isolated from blood cultures of pediatric patients. These microbes represent a small percentage of the total number of positive blood cultures recovered from children. This may be due partly to the difficulty in isolating and identifying these organisms. There is, however, a growing awareness of the role of anaerobic organisms in pediatric infection, including bacteremia.[1-5]

This communication presents the combined experiences of two medical institutions in the isolation of anaerobic microorganisms from blood cultures obtained from infants and children. The clinical data were reviewed and correlated with the bacteriological findings, and only cases of patients with clinical bacteremia are reported. Included are neonatal bacteremia, bacteremia associated with underlying disease and with artificial devices (neurological and cardiovascular shunts), and bacteremia in normal subjects.

MATERIALS AND METHODS

Medical records of all children with anaerobic bacteremia who were hospitalized between Jan 1, 1974, and March 1, 1975, at UCLA Medical Center, and between Jan 1, 1976, and March 31, 1980, at Children's Hospital National Medical Center (CHNMC), Washington, DC, were reviewed retrospectively. The diagnosis of anaerobic bacteremia was made when anaerobic bacteria were isolated from blood cultures and their recovery correlated with the clinical findings.

All blood cultures were inoculated at the patient's bedside into 50 mL of trypticase soy broth containing 0.03% sodium polyanetholesulfonate at UCLA Medical Center, or into trypticase soy broth containing 0.05% sodium polyanetholesulfonate at CHNMC. They were incubated at 35 °C for a period of seven days (UCLA) or ten days (CHNMC). All bottles were inspected daily for evidence of macroscopic growth. In addition, a blind subculture of macroscopically negative bottles was done at 24 and 48 hours. Approximately 0.1 mL of broth from each bottle was inoculated onto two chocolate agar plates and incubated at 35 °C in 7% CO_2 and in an anaerobic jar. All plates were examined for growth at 24 and 48 hours. All macroscopically positive blood cultures were subcultured to appropriate plating media as determined by Gram-stain characteristics. The anaerobic jar sys-

tem was used for incubation of subcultures from bottles suspected of containing anaerobes and for most biochemical tests. Anaerobic plating media were preincubated for 48 hours under an atmosphere of CO_2 as described previously.[6] Biochemical identification of anaerobic strains was done by methods previously described.[6,7] Gas chromatography of metabolic end products was done by the methods of Holdeman and Moore.[8]

RESULTS

The clinical and bacteriological data of 28 pediatric patients with anaerobic bacteremia are presented in Table 1. There were 16 males and 12 females with an age span from 2 days to 14 years (average, 7 years 4 months). The Figure shows the distribution of anaerobic bacteria isolated as a function of age. The duration of symptoms prior to therapy was one to 23 days (average, 6.6 days).

Twenty-nine anaerobic isolates were recovered from the 28 patients. No aerobic bacteria were isolated from these patients. In descending frequency, organisms isolated were as follows: *Bacteroides* sp in 14 patients (11 in the *B fragilis* group); Gram-positive anaerobic cocci in four; *Propionibacterium acnes* in four; *Clostridium* sp in four; and *Fusobacterium* sp in three (Table 2).

Source of Entry

The probable portals of entry for the blood culture isolates are given in Table 2. The gastrointestinal (GI) tract predominated (13 cases), followed by the respiratory tract (ear, sinus, and oropharynx, seven); the lower respiratory tract (three); cardiovascular shunts and neurological shunts (three); and skin and soft tissue (three). When the GI tract was the probable portal of entry, *Bacteroides* sp (eight isolates, including five of the *B fragilis* group) and *Clostridium* sp (four isolates) were the organisms most frequently recovered from blood. The predominant anaerobic organisms recovered in association with infections of the ear, sinus, and oropharynx were *Peptococcus* sp (in four cases) and *F nucleatum* (in two cases). *Propionibacterium acnes* was grown in cultures taken from four patients, three of whom had artificial cardiac valves or ventriculoatrial shunts. Two of these patients also were initially observed to have meningitis caused by a similar organism. All lower respiratory tract infections that served as a probable source of bacteremia were due to isolates belonging to the *B fragilis* group.

No obvious focus of infection was noted in six patients; however, it is of interest that all of these patients had some GI problem that might have served as a source of the bacteremia. Of further interest is that four of these patients had bacteremia caused by *Clostridium* sp.

Extravascular Infection

Anaerobic organisms recovered from blood were also isolated from other infected sites in 16 (57%) of the patients. In eight of the 16 patients, anaerobic bacteria were mixed with other anaerobic and/or with aerobic organisms (two to five bacteria per specimen of pus). Extravascular sites from which anaerobic organisms were recovered included the following: abscesses, four cases; CSF, three; peritoneal fluid, four; tracheopulmonary aspiration, two; sinuses, two; and sinus and subdural empyema, one. Seven of the eight children who had soft-tissue abscesses or local collections of pus required surgical drainage. Some of these patients had recurrent or persistent bacteremia until proper surgical drainage was performed. Four patients also had extravascular collections of pus; however, anaerobic organisms were not recovered from these sites either because anaerobic cultures were not obtained or because the specimens were inappropriately transported.

e 1.—Clinical Data on 28 Patients With Bacteremia due to Anaerobic Bacteria

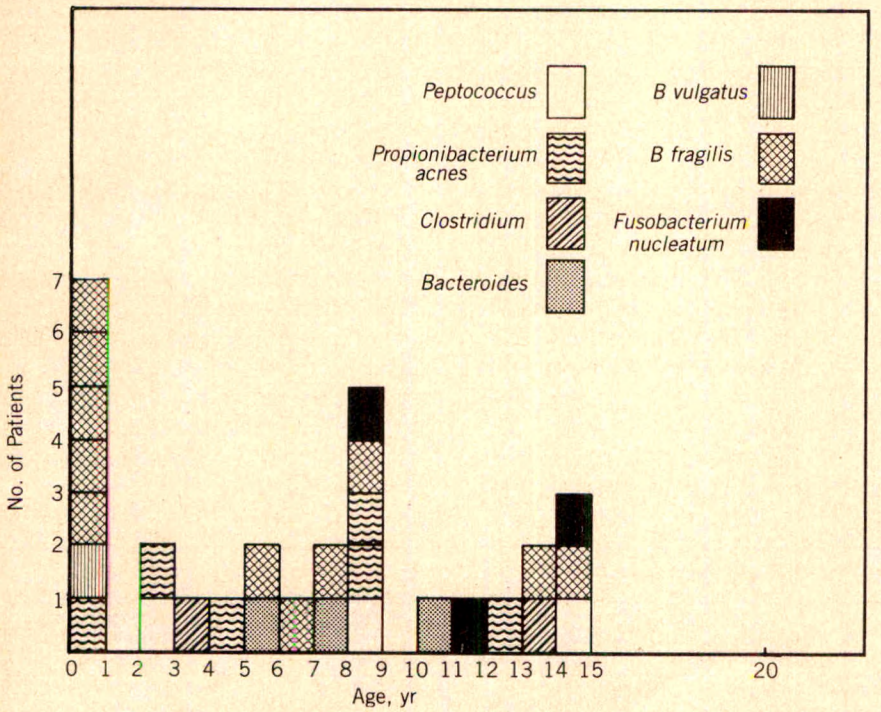
Probable Source	Underlying Conditions	Other Complications	Antimicrobial Therapy	Results	Other Infectious Sites With Similar Bacteria
Abscesses (2),* sinusitis (1)	None (3)	Subdural empyema (1); meningitis (1)	Penicillin G potassium (1); ampicillin sodium (1); oxacillin sodium (1)	Cured (3)	Subdural empyema and sinus (1); abscess (1)
Cardiovascular shunts (3); periorbital cellulitis (1)	Hydrocephalus (1)	Meningitis (2)	Penicillin (2); methicillin (1); ampicillin (1)	Cured (3); died (1)	CSF (2)
Gastrointestinal (GI) tract (4)	Sickle cell disease (2)	None (4)	Penicillin (2); ampicillin (2)	Cured (4)	None (4)
Perforation viscus (2); ileus (1)	Acute lymphocytic leukemia (1)	Peritonitis (1)	Clindamycin hydrochloride (2); carbenicillin disodium (1)	Cured (3)	Peritoneal fluid (2)
Perforated appendix (3); pneumonia (3); abscesses (3); GI tract (1); necrotizing enterocolitis (1)	Mental retardation (2); acute lymphocytic leukemia (1); selective IgG deficiency (1); prematurity (1); recent hip surgery (1)	Meningitis (2); peritonitis (2); septic shock (1); empyema (1)	Clindamycin (6); penicillin (3); chloramphenicol sodium succinate (2); ampicillin (2); carbenicillin (1)	Cured (7); died (4)	Abscess (3); tracheopulmonary aspiration (2); peritoneal fluid (2); CSF (1)
Sinusitis (2); perforated appendix (1)	Chronic otitis media (1)	Subdural empyema (1); periorbital cellulitis (1)	Chloramphenicol (2); clindamycin (1)	Cured (3)	Sinuses (2)

*Number of cases in parentheses.
†In one case, *Peptococcus* sp was also recovered in the blood culture.

Antimicrobial Therapeutics

Penicillins (except carbenicillin disodium) were used in the treatment of 16 patients; clindamycin hydrochloride, in nine; chloramphenicol sodium succinate, in four; and carbenicillin, in two. Twelve patients received a combination of two or three of these antibiotics for treatment of organisms present at other infection sites. The average duration of therapy in the patients who recovered was 20 days (range, seven to 72 days), and the duration of therapy was related to the presence and severity of other infectious sites and complications (Table 2). Therapy was longest in the treatment of meningitis, wound, abscess, sinusitis, and empyema.

Bacteriological cure of the bacteremia occurred in 23 patients. Of the five children who died, three died within four days after therapy was instituted. Two of these were newborns. One child had bacteremia and meningitis caused by *P acnes*. The second, a newborn with anaerobic bacteremia, also had meningitis and perinatal pneumonia. *Bacteroides vulgatus* was isolated from both sites and the blood culture. Because of a delay in the identification of this organism, the child was inappropriately treated. A third patient, a 6-year-old suffering from acute lymphocytic leukemia, had a perirectal abscess and died in spite of vigorous antimicrobial therapy and drainage of the abscess. The fourth child, a 5-year-old who had a selective IgG 2 deficiency and severe anoxic brain damage, had bronchopneumonia and sepsis due to *B fragilis*. The fifth child who died, a premature newborn, suffered from necrotizing enterocolitis, perforation of the colon, and sepsis due to *B fragilis*.



Age distribution of patients with anaerobic bacteremia.

Table 2.—Probable Sites of Source of Bacteremia

Bacteria	Ear, Sinus, Oropharynx	Skin, Soft Tissue	Shunts	Gastrointestinal Tract	Lower Respiratory Tract	Total
Peptococcus sp	4†					4
Propionibacterium acnes	1		3			4
Clostridium sp				4		4
Bacteroides sp				3		3
B vulgatus					1	1
B fragilis		3		5	2	10
Fusobacterium nucleatum	2†			1		3
Total	**7**	**3**	**3**	**13**	**3**	**29†**

*According to number of cases of anaerobic bacteria.
†One case represents a mixed infection with *Peptococcus* sp and *F nucleatum*.

Meningitis

In five (18%) of the children, meningitis occurred that was associated with *B fragilis* (two cases), *P acnes* (two), and *Peptococcus* sp (one). A direct extension of the organism from an infection site to the meninges might have occurred in two of these children, both of whom had surgical drainage of their local collection of pus. One of these patients had pansinusitis and required a Caldwell-Luc procedure, where a direct extension of the inflammation to the subdural space through the cribriform plate was demonstrated. Ethmoid drainage and frontal craniotomy yielded pus from the sinus as well as the subdural space. The child with pilonidal sinus had surgical drainage and subsequent removal of the sinus tract.

COMMENT

Anaerobic bacteremia has rarely been described in pediatric patients.[9,10] In one study, anaerobic organisms were recovered in six of 34 children who required general anesthesia and nasotracheal intubation for dental repair.[11] Another study documented bacteremia in 28 children who were undergoing dental manipulations.[12] Among the 28 isolates recovered, 21 were anaerobes (*Propionibacterium* sp, nine; *Veillonella alcalescens*, five; *B melaninogenicus*, three; *Peptostreptococcus* sp, two; and *Eubacterium* sp and *Fusobacterium* sp, one each).

In a survey of anaerobic infections in children, blood cultures have been found to be the second most frequent source of anaerobic organisms.[1] The

predominant isolate from blood cultures (56% to 65%) is *P acnes*,[1,2] a normal inhabitant of the skin. Many of these isolates may reflect contamination of the blood cultures by the skin flora; however, *P acnes* can cause bacteremia, especially in association with shunt infections.[13] All of the patients with *P acnes* bacteremia included in our study had clinical infection and all but one responded to antimicrobial therapy. Furthermore, two of them had meningitis caused by this organism after installation of cardiovascular shunts. The possibility that some of the other isolates recovered from our patients were contaminates is unlikely. The high incidence of recovery of similar bacteria from extravascular sites, the lack of recovery of aerobic isolates, and the response to therapy support this contention.

Bacteroides fragilis, anaerobic Gram-positive cocci, and *Fusobacterium* sp were the other anaerobic organisms most commonly isolated from blood cultures in three recent studies.[1-3] Most of the patients described in these studies were over 6 weeks of age and suffered from chronic debiliating disorders such as malignant neoplasms, immunodeficiencies, or chronic renal insufficiency, along with long-term prognosis. *Bacteroides* sp were also isolated frequently after perforation of viscus and appendicitis.[14,15]

Neonatal Bacteremia

A recent report[4] described anaerobic bacteremia in 23 newborns and reviewed 57 additional cases from the literature. The yield of anaerobic bacteria in 23 newborns seen over a period of 3.5 years represented 1.8 cases per 1,000 live births and accounted for 26% of all instances of neonatal bacteremia at that hospital. The bacteremia episodes were associated with prolonged labor, premature rupture of membranes, maternal amnionitis, prematurity, fetal distress, and respiratory difficulty. In that series, the patients with neonatal anaerobic bacteremia had better prognoses than did newborns with bacteremia caused by facultative bacteria. Only one patient of the 23 (4%) died; however, the mortality from the cases of anaerobic bacteremia reviewed from the literature was 26%. Neonatal sepsis due to facultative organisms has been reported to range from 30% to 44%.[16,17]

The isolation of nonhistotoxic *Clostridium* sp from 18 newborns with bacteremia has been described.[18] Bacteremia was also found to be associated with necrotizing enterocolitis of the newborn. *Clostridium butyricum* was recently isolated from blood cultures obtained from 12 newborns with that disease.[19]

Bacteremia in newborns has also been attributed to *Bacteroides* sp[20-22] and *F nucleatum*,[23] organisms that can be acquired during the infant's passage through the birth canal. Moreover, six episodes of *B fragilis* bacteremia associated with perinatal pneumonia were reported recently.[1,24] The two newborns in our series died within four days of therapy. These patients were infected by organisms of the *B fragilis* group and received inappropriate antimicrobial therapy. Though the occurrence of bacteremia in newborns is infrequent, our experience indicates the need for proper antibiotic coverage of the newborn against *B fragilis*.

Predisposing Factors

Predisposing factors to anaerobic bacteremia in adults include malignant neoplasms,[25,26] hematologic disorders,[27] transplantation of organs,[28] recent GI or obstetrical gynecological surgery,[26,27,29] intestinal obstruction,[30] diabetes mellitus,[26] postsplenectomy,[28] use of cytotoxic agents or corticosteroids,[26] and use of prophylactic antimicrobial agents for "bowel preparation" prior to surgery.[26,29]

Predisposing conditions were also noted in our patients. Two had malignant neoplasms, two suffered from hematologic abnormalities, and one had an immune deficiency. It is of interest that 82% of the bacteremias in our series of patients occurred in children who had no immunosuppression or malignant neoplasms, in contrast to another study[10] where anaerobic bacteremia occurred more frequently in children with these predisposing factors.

As reported in adults, the strain of anaerobic organisms recovered depended to a large extent on the portal of entry and the underlying disease.[9] Our findings support previous studies of adults[31] and children[10] that report that *Bacteroides* sp, including the *B fragilis* group, were the predominant isolates from patients in whom the GI tract was the probable portal of entry. As previously reported in adults,[32] we found the ear, sinus, and oropharynx as possible portals of entry that predisposed patients to bacteremia with *Peptococcus* sp and *Fusobacterium* sp. This is not surprising since these organisms are part of the normal flora of such anatomical sites and can be involved in local infections.[9]

Pneumonia occurred in three of our patients subsequent to bacteremia with organisms belonging to the *B fragilis* group. This has also been noted in adults[33] and newborns.[4] Though *Bacteroides* accounted for the majority of the episodes of bacteremia in our study, other studies have shown relatively infrequent isolation of these organisms in children[33] except during the neonatal period.[4]

The clinical features of anaerobic bacteremia in our patients were not much different from other types of bacteremia in children; however, a relatively longer period was needed before an etiologic diagnosis could be made. This can be a result of the smaller volume of blood drawn from children for culture inoculation and the longer time needed for growth and identification of anaerobic organisms.

Certain other serious concomitant complications were also present in our patients. The most frequent complication was meningitis, which occurred in five patients. Peritonitis occurred in three patients, subdural empyema in two, and septic shock in one. Though many of the children were seriously ill, most responded well to therapy.

The mortality following anaerobic bacteremia in our series was 18% (five cases) and depended on such factors as age of the patient, underlying disease, nature of the organism, speed with which the diagnosis was made, and surgical or medical therapy instituted. This mortality was similar to that reported in adults.[9] Of the three infants who died, two were newborns

and one was 8 months old. Four patients were infected with organisms of the *B fragilis* group that were resistant to penicillin; inappropriate antimicrobial therapy was administered in two of these cases, due to the length of time needed for identification of the organisms; and the other two patients had underlying disorders that further aggravated their conditions. The fifth child who died had a ventriculoatrial shunt that was infected with *P acnes*, along with severe hydrocephalus and mental retardation.

Prolonged therapy with antimicrobial agents alone was apparently adequate for most patients. When anaerobes resistant to penicillin, such as the *B fragilis* group, are suspected or isolated, alternative medication such as clindamycin, chloramphenicol, carbenicillin, or ticarcillin disodium should be administered. Surgical drainage is essential when pus has collected. Organisms identical to those causing anaerobic bacteremia were recovered from other infected sites in 15 patients (58%). No doubt these extravascular sites may have served as a source of persistent bacteremia in some cases; however, the majority of patients recovered completely when prompt treatment with appropriate antimicrobial agents was instituted before any complications developed. The early recognition of anaerobic bacteremia and administration of appropriate antimicrobial and surgical therapy play a significant role in preventing mortality and morbidity in pediatric patients.

The staffs of the Clinical Microbiology Laboratories at Children's Hospital National Medica Center, Washington, DC, and the UCLA Medica Center provided help and cooperation; Linda Harteker, MS, assisted in the preparation of the manuscript.

Cerebellar Ataxia, Opsoclonus, and Occult Neural Crest Tumor

Abdominal Computerized Tomography in Diagnosis

Morris Kinast, MD; Howard S. Levin, MD; A. David Rothner, MD; Gerald Erenberg, MD; Jeffrey Wacksman, MD; James Judge, DO

• A 9-month-old female with opsoclonus and ataxia was examined. Computerized axial tomography (CT) of her abdomen identified a retroperitoneal mass of neural crest origin that was not recognized by more conventional roentgenographic methods. The syndrome of cerebellar ataxia, myoclonus, and opsoclonus, and its relationship to neural crest tumors is reviewed along with the usefulness of abdominal CT.

(*Am J Dis Child* 134:1057-1059, 1980)

Opsoclonus, defined as periodic, jerking, ataxic, conjugate eye movements occurring in all planes, was first described in 1927 by Orzechowski.[1] The anatomic focus for opsoclonus is thought to be in the cerebellum.[2] Orzechowski noted the association of opsoclonus with cerebellar ataxia and myoclonus. Kinsbourne, in 1962, further described this triad in his report on six infants so affected.[3]

In 1968, Solomon and Chutorian[4] recognized the association of cerebellar ataxia, opsoclonus, and/or myoclonus with occult neuroblastoma. Today, it is generally accepted that a child with cerebellar ataxia and opsoclonus should be thoroughly examined for an occult neuroblastoma.

This article suggests that conventional radiology may not be sufficient for identification of all cases of occult neural crest tumors.

REPORT OF A CASE

A 9-month-old female was admitted for evaluation of opsoclonus and ataxia. She had been well until six weeks before admission when diarrhea developed and lasted five days. After the diarrhea cleared, the patient remained irritable and had intermittent jerky eye movements. One week later, truncal ataxia developed and became progressively worse. She was admitted to a local hospital where the examination included normal chest roentgenography, intravenous pyelography, electroencephalography, and computerized axial tomography (CT). The patient was treated with 40 IU of corticotropin, daily, with subsequent improvement of her eye movement and balance problems. She was then transferred to the Cleveland Clinic Foundation for further observation. The infant's prior development had been normal; she was able to attain a sitting position by herself and transfer objects from one hand to another.

On admission, physical examination showed an irritable child with frequent, intermittent jerking of her eyelids associated with chaotic eye movements. Extraocular movements were full. Muscle tone was markedly decreased. The patient had gross truncal ataxia and was barely able to sit alone when propped up. Mild limb ataxia was present. Deep tendon reflexes were normal. There was no myoclonus. The results of general examination were normal; no abdominal mass was palpable.

Laboratory findings included normal EEG, CT of the thorax, and 24-hour urine assay for catecholamines. The intravenous pyelogram (IVP) was also normal. Computerized tomography of the abdomen showed a mass of increased density in the mid-retroperitoneal space (Fig 1).

The patient underwent an exploratory laparotomy, and a 1.5 × 0.5 × 0.3-cm paraaortic retroperitoneal mass was excised. Postoperatively, she was treated with 30 mg of prednisone daily. After one month, the patient was beginning to pull herself to a sitting position; there were neither chaotic eye movements nor truncal ataxia, but there was persistent hypotonia. Three months after surgery, at which time she was receiving 5 mg of prednisone daily, the results of a neurologic examination were normal except for hypotonia. She was able to sit alone and pull herself to a standing position. The patient had a vocabulary of five words.

PATHOLOGIC FINDINGS

The resected specimen consisted of irregular, resilient, noncalcified, pink-white fibrous tissue with focal areas of brown nodularity. Microscopic examination showed nodules of mature neuroganglionic tissue, nerve, and fibroadipose tissue. The neurogan-

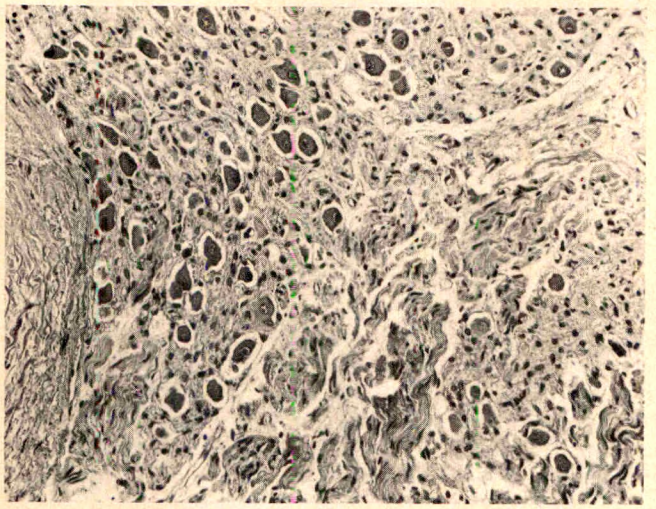

Fig 2.—Retroperitoneal mass showing benign ganglion cells admixed with Schwann cells growing, in part, in fascicular pattern (hematoxylin-eosin stain, original magnification ×200).

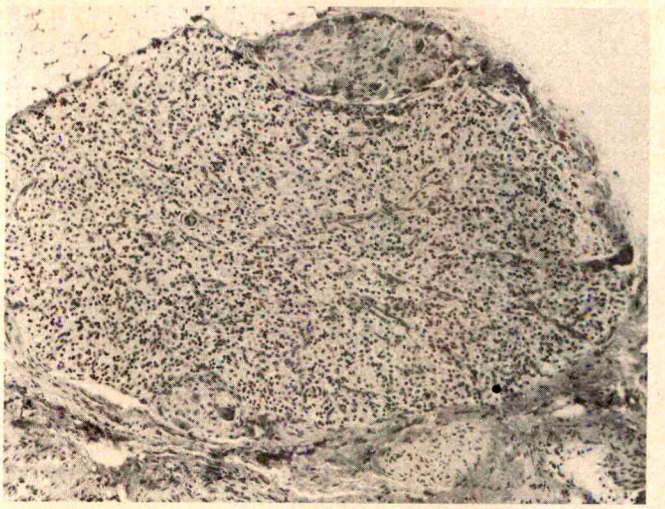

Fig 3.—Solitary, oval, 1.0-mm structure found at periphery of mass. It is encapsulated and divided by capillaries (hematoxylin-eosin stain, original magnification ×100).

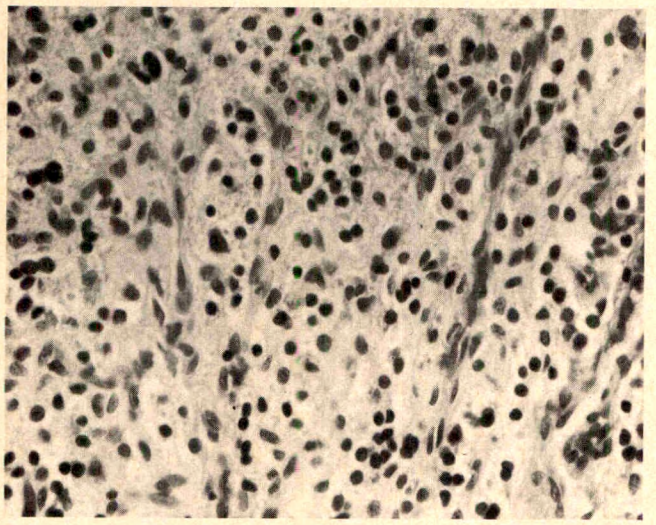

Fig 4.—Photomicrograph of Fig 3 at higher magnification. Elongated capillary structures divide nodule. These demarcate cells with round, dark nuclei and cells with more elongate vesicular nuclei. Cytoplasmic borders are indistinct and background has fibrillar character (hematoxylin-eosin stain, original magnification ×200).

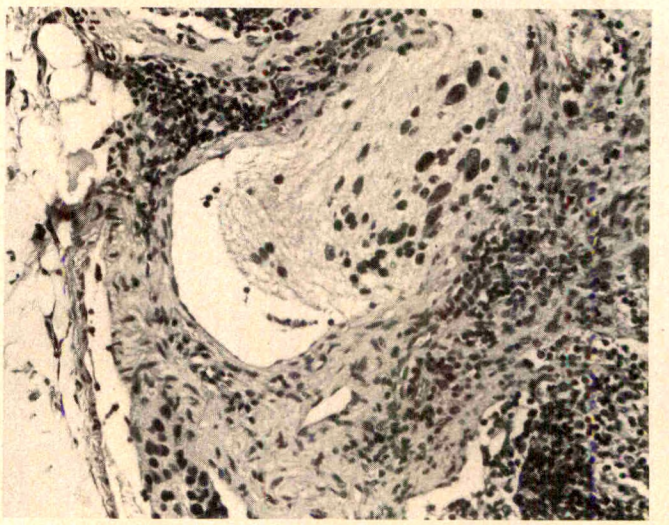

Fig 5.—Periphery of lymph node within retroperitoneal mass showing intrasinusoidal cells in eosinophilic, fibrillar background. Some cells are elongate, enlarged, and have character of ganglion cells (hematoxylin-eosin stain, original magnification ×200).

glionic tissue consisted of benign, mature ganglion cells and adjacent Schwann cells growing partly in a fascicular pattern (Fig 2). The ganglion cells contained reddish cytoplasm and vesicular nuclei with prominent nucleoli and fine chromatin. At the periphery of one section was a solitary, oval, 1.0-mm structure encapsulated by fine collagen and partly surrounded by neuroganglionic tissue (Fig 3). The structure was more cellular than the remainder of the tissue, lobulated, and divided by capillaries (Fig 4). Within roughly lobulated areas there were seen clusters of round cells with granular cytoplasm and dense nuclei that were the size of small lymphocytes. In the peripheral sinus of one lymph node, within a fibrillar eosinophilic background, there were cells of varied sizes with round to elongated nuclei and occasionally prominent nucleoli having the appearance of ganglion cells (Fig 5).

The original sections that did not show the ganglion-type cells in a lymph node were reviewed by several surgical pathologists, pediatric pathologists, and neuropathologists. Interpretations varied from ganglioneuroma with "neuroblastoma in situ" to benign neuroganglionic tissue with a paraganglial rest.

The discrete area believed by some to be neuroblastoma in situ appeared more organized, well defined, and noninvasive than the usual neuroblastoma. Although these cells had more abundant cytoplasm than the usual cells of neuroblastoma and although their appearance suggested a benign

paraganglial rest, the finding of immature ganglion cells in the peripheral sinus of a lymph node argued strongly for the neoplastic character of the lesion. The finding of fibrillar material and ganglion cells in the peripheral sinus of a lymph node suggested a maturing neural crest neoplasm. It was not possible to determine whether the tumor represented (1) a neuroblastoma that had metastasized and almost completely differentiated to a ganglioneuroma, (2) a ganglioneuroma with a neuroblastic focus from its inception, or (3) a tumor that was predominantly a mature ganglioneuroblastoma with local metastasis to a lymph node.

COMMENT

Acute cerebellar ataxia of childhood has many causes. When the ataxia is associated with opsoclonus there is often an occult neuroblastoma present. Roberts and Freeman[5] analyzed the methods of diagnosis of neuroblastoma in 25 reported cases of acute cerebellar ataxia and found that 56% were recognized by chest roentgenogram, 36% by physical examination, and 8% by abdominal roentgenogram. In our patient, no mass was recognized by any of these methods. In addition, results of an IVP and 24-hour urine assay for catecholamines were normal. The diagnosis was made only by CT of the abdomen. The usefulness of the body scanner for the diagnosis of abdominal lesions in children has been demonstrated by Leonidas et al.[6] In their study, however, abdominal CT and IVPs were abnormal in all patients with retroperitoneal masses. To our knowledge, our case is the first report of a retroperitoneal neural crest tumor diagnosed solely by abdominal CT.

Neuroblastomas are well known to undergo spontaneous regression by several mechanisms, including cytolysis and/or maturation into a ganglioneuroma.[7] Our patient's tumor was composed of predominantly mature neuroganglionic cells, with a single focus of cells thought to be neuroblastoma and a focus of ganglion cells in the peripheral sinus of a lymph node. It was not possible to determine whether the mass principally represented a ganglioneuroma from its inception or whether the tumor was a neuroblastoma that was differentiating into a ganglioneuroma. Had the tumor remained undiagnosed, it may have undergone spontaneous regression. Few autopsies have been performed on children with cerebellar ataxia and opsoclonus without associated neuroblastoma. It is tempting to speculate, as Bray et al[8] did, that some of these children actually have neuroblastomas that are undiagnosed by conventional techniques and subsequently undergo spontaneous regression. The unusual histologic findings in this case suggest the possibility that some of the reported cases of neuroblastoma and ganglioneuroblastoma in association with cerebellar ataxia represent entities that differ from the classic forms in histologic composition and biologic evolution. These cases should be assembled and critically reviewed in an attempt to identify the histologic and biologic features.

Surgical removal of the retroperitoneal mass resulted in dramatic improvement of our patient's neurologic problems. Such a favorable response, however, does not always occur, and it is possible that our patient will have a relapse. Neurologic deficits may persist despite complete surgical cure of the neuroblastoma. Senelick et al[9] reviewed 22 reported cases and found that only 18% of the patients became free of neurologic abnormalities after treatment of the neuroblastoma, 82% had residual cerebellar signs, and 36% were mentally retarded. Although the incidence of neurologic sequelae is high, the prognosis for survival is good. The two-year survival rate for children with neuroblastoma and cerebellar ataxia is reported to be 84% to 91% compared with a survival rate of only 10% to 29% for the overall number of patients with neuroblastoma. In both groups, the survival rate is best among children less than 1 year old at the time of diagnosis.[10]

The pathogenesis of the disorder is unknown. Postmortem examinations do not reveal tumor metastases to the cerebellum. In two reported necropsies of subjects with this syndrome, one showed mild demyelination adjacent to the dentate nucleus and another showed marked loss of Purkinje's cells.[11] Suggested pathogenetic mechanisms include (1) cross reaction of antibodies to the neural crest tumor with cerebellar cells, the resulting antigen-antibody reactions cause the cerebellar dysfunction; (2) infection of both neural crest tissue and the cerebellum with a neurotropic virus that causes both tumor formation and cerebellar dysfunction; and (3) release by the tumor of a metabolite that disrupts normal cerebellar function.[8]

We believe that if a child has cerebellar ataxia and opsoclonus, and conventional methods fail to identify a neoplasm, whole-body CT should be performed in an effort to determine if an occult neuroblastoma or other neural crest tumor exists.

Local Immunity in Mumps Meningitis

Tsuneo Morishima, MD; Mitsunobu Miyazu, MD; Takao Ozaki, MD; Shin Isomura, MD; Sakae Suzuki, MD

• Titers of antibodies to mumps and measles virus and interferon activity were measured in sera and CSF obtained from 15 children with mumps meningitis. Antibody to mumps virus was found in 11 of 15 CSF samples. Evaluation of the CSF-serum ratio for antibodies to both viruses showed a substantially higher ratio for antibody to mumps virus. The ratio of IgG/IgM antibody activity to mumps virus was greater in CSF than in sera. These results could be attributed to antibody synthesis, particularly IgG, in the CNS. Titers of antibodies to mumps virus in CSF increased rapidly, reaching a peak four to ten days from onset of meningitis, and swiftly decreased thereafter. During the acute phase, interferon activity was found in almost all cases ranging from 16 to 128 IU/mL in sera, and 4 to 16 IU/mL in CSF. In cases of mumps meningitis that followed the usual clinical course, interferon disappeared within a week, whereas it persisted in the CSF in cases of persistent pleocytosis.

(*Am J Dis Child* 134:1060-1064, 1980)

It is well known that many viruses can invade the CNS and cause various diseases (eg, meningitis, encephalitis, postinfection encephalitis, and degenerative diseases).[1] In some cases, the mortality is high and the sequelae serious. While the recent development of effective vaccines has resulted in prevention of many viral diseases,[2] once an infection of the CNS is established, effective treatment is virtually impossible. It is still unclear how the host defense mechanisms work to eliminate the virus at the infected site.

Using experimental animals, research on the local humoral and cellular immunity of the CNS has been undertaken,[3-5] and it has become clear that cerebral tissues are capable of independent immunologic responses to viral infection. However, aside from some cases such as subacute sclerosing panencephalitis[6] and meningitis caused by echovirus,[7] studies in humans are scarce.

We have obtained paired sera and CSF from children with mumps meningitis. Using these samples, we studied the production of antibody in the CNS and changes in interferon activity in CSF during infection.

SUBJECTS AND METHODS

Patients

The study group consisted of 15 children with mumps meningitis and three with mumps parotitis in which meningitis did not occur. The children were between 3 and 11 years old. They were admitted to the pediatric wards of Nagoya University Hospital, Handa Hospital, Anjo Hospital, and Okazaki Hospital from May 1977 to June 1978. Fifteen of the 18 were male. The diagnosis of mumps parotitis was based on the typical swelling of the parotid gland and serologic evaluation. The diagnosis of meningitis in these children was confirmed by clinical manifestation (fever, headache, vomiting, and stiff neck) and by lymphocytic pleocytosis in their CSF several days after the onset of parotitis. The cell count of CSF ranged from 115 to 1,160 cells/cu mm and the percentage of mononuclear cells ranged from 50% to 100%. Four of the children, cases 12 through 15 in Table 1, showed persistent pleocytosis (cell count, ≥100/cu mm seven to ten days after the onset of meningitis). Although clinical symptoms persisted for a few days in these four cases, all patients recovered completely within three weeks after the onset.

Materials

Sera and CSF that were collected within a few hours of each other were obtained from patients in both the acute and convalescent phases. All specimens were stored at −20 °C until tested.

Hemagglutination Inhibition (HI) Test

Paired serum and CSF specimens were examined, in parallel, for hemagglutinating antibodies to mumps and measles virus. The HI test was based on that described by Rosen.[8] The titers are given as the reciprocal of the maximum dilutions of serum or CSF that showed HI activity. Serum dilutions started at 1:10 for mumps virus and 1:16 for measles virus. Dilutions of CSF were started at 1:2. Blood-stained or xanthochromic samples of CSF were not tested.

Indirect Immunofluorescence

To determine the class specificity of the antibodies to mumps virus, an

indirect immunofluorescent assay was performed as described previously.[9] Mumps virus-infected monkey kidney cells were used as antigens. Serial dilutions of CSF and sera from five patients, and fluorescein isothiocyanate-conjugated antihuman IgG and IgM were used as the primary and secondary antibodies, respectively.

Interferon Assay

To assay interferon, CSF and sera were dialyzed overnight at a pH of 2; the pH was adjusted to a pH of 7.0 before assay. The assay was performed according to the cytopathic effect inhibition method in FL cell[10] monolayers, using vesicular stomatitis virus (VSV) as a challenge virus. A modification of the semi-micromethod described by Havell and Vilček was used.[11] Individual wells of a 96-well tissue culture plate were first filled with 50 μL of Eagle's minimum essential medium (MEM). From each sample 50 μL was added to the first well that contained an equal volume of medium, and twofold serial dilutions were made using an automatic diluter. Each well was then seeded with 50,000 FL cells in 50 μL of MEM supplemented with 5% fetal calf serum (FCS). After 20 hours of incubation at 37 °C in a 5% CO_2 incubator, the media was discarded and each well was then infected with 100 units of a 50% tissue culture infective dose ($TCID_{50}$) of VSV in 100 μL of MEM and FCS. The cells were observed microscopically 36 to 48 hours after inoculation of the virus. At this time, the control cells showed complete destruction by the virus. The highest dilutions of the sample that caused 50% protection of cells were considered the end points. In this microassay, 1 interferon unit/mL was equal to 2.0 IU/mL. Each sample of CSF of serum was titrated in duplicate. To check species specificity of this activity, mouse L cells[12] were used as target cells.

RESULTS

HI Antibody Titer in Sera and CSF

Table 1 gives HI titers of antibodies to mumps virus in convalescent sera and CSF from 15 children with mumps meningitis. All of the sera were positive for antibodies to mumps virus with titers ranging from 20 to 320. Of the 15 CSF samples, nine were positive with titers ranging from 2 to 16. Cases 9 and 11 did not have antibodies to mumps virus in convalescent CSF; however, antibodies were present during the acute phase of meningitis with titers of 2. To summarize, antibody to mumps virus was found in 11 of 15 samples of CSF during the illness.

Table 1 also gives the HI titer of antibodies to measles virus. Except for three cases (case 1, 5, and 7), titers of 32 or more were found in sera, whereas, in CSF, an HI titer of two could be detected in only two cases. The CSF-serum ratios of antibodies to mumps and measles virus were determined. The antibody ratios for mumps virus ranged from approximately 1:20 to 1:40. The antibody ratios for measles virus were clearly lower, as shown by a substantial difference in the CSF-serum ratio for the two viruses.

Antibodies to mumps virus were found in sera from three patients with uncomplicated mumps meningitis at titers ranging from 40 to 160, but there was no evidence of antibody activity in their CSF.

IgG and IgM Fluorescent Antibody (FA) Titer

To determine the class of immunoglobulin in CSF and sera, indirect immunofluorescence was performed. Table 2 gives FA titers of IgG and IgM to mumps virus in five patients' CSF and sera. In four cases, the ratio of IgG/IgM FA titer was greater in CSF than in sera. This result suggests that the antibody response in the CNS may be dominated by IgG synthesis.

Kinetics of Antibodies to Mumps Virus

The change in HI titer of antibodies to mumps virus with time was investigated in sera and CSF. Figure 1 shows the HI titer to mumps virus in sera and CSF of the 15 cases in terms of days after the onset of meningitis. As shown in this figure, in all sera, the

antibody titer increased during the convalescent phase over that seen in the acute phase. Antibodies in the CSF, however, were detected very early (one to two days after onset) in three cases. By day 4 to 10 the antibody titer peaked in many cases and sharply declined thereafter. Only one case possessed antibodies in the CSF 25 days after the onset of the illness. Thus, the antibody titer in CSF rose at first but soon declined; an obvious difference from the serum antibody response. These studies indicate that an independent humoral immune response occurs in the cerebral cavity in mumps meningitis.

Interferon Activity

Figure 2 shows interferon levels in sera and CSF of the 15 patients with mumps meningitis. In the acute phase, 16 to 128 interferon units/mL were found in all serum samples. In many cases, these levels disappeared within ten days. On the other hand, in 14 of 15 CSF samples, 4 to 16 interferon units/mL were detected in the acute phase. In cases that followed the usual clinical courses of mumps meningitis, such levels declined by about day 7. However, in four patients with persistent pleocytosis, three (cases 12, 14, and 15, indicated by asterisk) continued to display interferon activity for seven to ten days. During this time, no interferon activity could be found in their sera. Interferon levels in the CSF diminished gradually, corresponding to the improvement of the CSF pleocytosis. In the three cases of uncomplicated mumps meningitis, however, no CSF interferon was detected during the infection.

The Role of Mononuclear Cells in CSF

To study the role of mononuclear cells in CSF, the relationship between the mononuclear cell count and HI titer of antibodies to mumps virus in CSF was examined. No positive correlation was apparent ($r = -.36$); however, there was a definite positive correlation between the mononuclear cell count and the interferon titer in CSF ($r = +.73$). Thus, it is believed that the greater the mononuclear cell populations, the higher the titer of interferon in CSF.

COMMENT

Viral infections of the CNS, while not frequent, can become very serious. As yet, there is no effective treatment available, with the possible exception of the use of vidarabine in cases of encephalitis due to herpes simplex virus.[13] In order to find an effective treatment, it is necessary to ascertain what defense mechanism operates at the actual site of virus invasion, which factor is activated first among immune systems, and what factor is blocked in a serious illness.

Recent experiments using mice have provided data on the role of local immunity in viral infections of the CNS. Hapel and Gardner[4] reported that in mouse meningitis caused by ectromelia virus, cytotoxic T cells appear in the CSF. We have found that in the cases of vaccinia meningitis in mice, 80% of the mononuclear cells appearing in the meninges are T cells, 12% are macrophages, while B cells are extremely rare.[14] These local T cells were observed to be virus-specific and were cytotoxic to vaccinia virus-infected cells. It has been suggested that the cell-mediated immunity in the brain can be separated from other systemic immune activities.

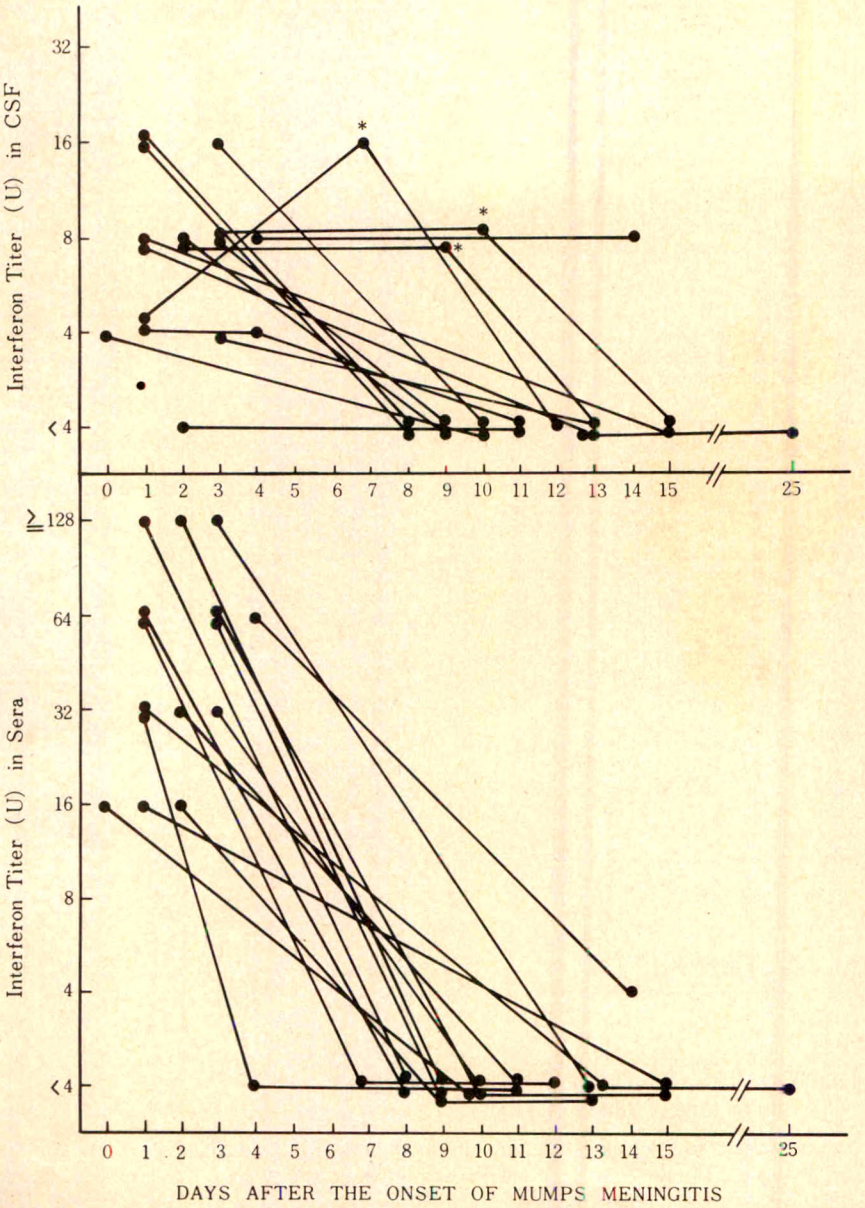

Fig 2.—Kinetics of interferon activity in sera and CSF from 15 patients with mumps meningitis. Asterisk indicates cases with persistent pleocytosis and prolonged interferon production in CSF. In our assay system, 1 interferon unit/mL was equal to 2.0 IU/mL.

Gerhard et al,[15] in their investigations of humoral immunity in viral infections of the CNS, studied immunoglobulin subtypes in CSF from mice infected with parainfluenza virus type 1 and concluded that independent antiviral antibody production occurred in the CNS. In cases of subacute sclerosing panencephalitis in humans, the observation of high titers of antibodies to measles virus in CSF was found to be due to independent production of antibody within the CNS.[6] However, reports on the immune responses of CNS in the case of ordinary acute viral infections are relatively rare.[7,16]

In this article, we have discussed antibody and interferon production in the CNS in cases of mumps meningitis. Comparison of the titers of antibodies in CSF and serum during the convalescent phase showed that the CSF-serum ratio of antibodies to mumps virus was higher than the ratio for measles virus. Therefore, antibodies to mumps virus in CSF are not caused by some serum antibody influx, but by the independent production of antibody within the CNS. Investigations of the transition in antibody production in CSF showed that antibody activity in CSF increased rapidly, reached a peak at four to ten days from the onset, and swiftly declined thereafter. Thus, the kinetics of antibody production in CSF were quite different from those in serum. In addition, the IgG/IgM ratio was greater in CSF than in sera. Therefore, IgG synthesis may be predominant in the CNS. This result coincides with the recent article by Frydén and Link.[17]

Gresser and Naficy[18] reported the existence of interferon activity in CSF in viral diseases of the CNS. However, to date, the role of local interferon has been unclear. We also found that interferon was present in CSF at a concentration of 4 to 16 IU/mL in the acute phase of mumps meningitis and disappeared within ten days. Long-lasting interferon production was detected in three cases of persistent pleocytosis. However, this prolonged interferon production disappeared with the improvement of the pleocytosis. In these cases, it is possible that interferon production continued because of the viral antigens that may have remained so long in the meninges. From these results, we propose that interferon activity in the brain might be a key factor in curbing the local spread of a virus. A positive relationship exists between these interferon levels and the mononuclear cell count in CSF, so these cells might contribute to interferon production in the CNS (in our unpublished data, these mononuclear cells are mainly T cells).

Recent studies on the mechanism of interferon production divide interferon into at least two types. Type 1, or standard interferon, is produced by nonlymphoid and lymphoid cells in response to viruses, polynucleotides, and endotoxin.[19] Type 2, or immune interferon, is a mediator of cellular immunity, a lymphokine, and produced by sensitized lymphocytes in response to specific antigens or antigen-antibody complexes.[20-22] The interferon measured in our laboratory was type 1 interferon, since the activ-

ity was found after treatment at a pH of 2. However, it is possible that type 2 interferon was also produced during these infections and was destroyed by the treatment at a pH of 2. Hooks et al[23] suggest that the production of type 2 interferon may contribute to immunologic aberrations in autoimmune diseases and may also protect the already compromised host from further viral infections. The role of type 2 interferon in viral infections of the CNS, particularly in those infections that are chronic or subchronic, should be investigated further.

John J. Hooks, PhD, Laboratory of Oral Medicine, National Institute of Dental Research, and Janice D. Longstreth, PhD, Laboratory of Microbial Immunity, National Institute of Allergy and Infectious Disease, National Institutes of Health, gave advice and assistance in preparation of this manuscript.

60 YEARS AGO IN THE AJDC

A Polyneuritic Syndrome Resembling Pellagra-Acrodynia (?) Seen in Very Young Children

A group of seventeen patients is reported who appeared with a combination of painful and red hands and feet, photophobia and redness of the eyes, restlessness, and at times delirium combined with alopecia, anorexia, and emaciation proceding to death. All were young children under 4 years of age and five were under a year. No fever or acute symptoms were described. There was no tendency to clustering geographically and the cases were seen in each of the preceding five years. Several patients died but the total number of deaths is not given. The clinical picture was one of misery: children would lie abed rubbing hands and feet, apathetic, and wretched. The tender hands, however, appeared to have diminished sensitivity to pinprick. The rash commonly went on to exfoliation. The finger and toe nails were entirely unaffected. Hair loss was caused by children pulling out hair by the handful. Teeth were commonly lost spontaneously with no prior apparent disease, caries, or gum disease. Mild leukocytosis occurred in some cases. There were several children who had a urinary tract infection. The disorder lasted from two to eight months. Treatment was of little avail. A number of children were gavage fed, thought to be of some benefit. No effect was derived from diphtheria antitoxin. Removal of diseased tonsils and adenoids appeared effective in some cases.

Various etiologies were discussed. Pellagra, while similar in some respects, was dismissed as less likely. Arsenic poisoning was excluded by study of the urine. Influenza, prevalent at the time, was considered but did not seem to have occurred in others living with the children and few had significant respiratory symptoms. Acrodynia or "epidemic erythema" was thought to have a number of features in common with this disorder.—Albert H. Byfield, MD, Department of Pediatrics, College of Medicine, State University of Iowa, Iowa City (20:347-365, November 1920).

Progressive Facial Hemiatrophy

Report of a Case Associated With Ewing's Sarcoma

Jan E. Paradise, MD; R. Beverly Raney, Jr, MD; Linton A. Whitaker, MD

• A child with progressive facial hemiatrophy (PFHA) later had Ewing's sarcoma develop. During seizures presumably related to her PFHA, she suffered pathologic fractures on two occasions. The second of these might have been avoided had her condition been better understood.

(*Am J Dis Child* 134:1065-1067, 1980)

Progressive facial hemiatrophy (PFHA) was first described by Parry[1] and Romberg[2] in the mid-19th century. Although PFHA generally begins during childhood, no mention of it appears in standard pediatric textbooks, and we have found only two references to it in the pediatric literature, on succeeding pages of a single publication.[3,4] Prompt recognition of PFHA is important, not only because effective cosmetic management is available, but also because failure to appreciate its various complications—in particular, unusual manifestations of epilepsy—may result in delayed or inappropriate therapy. We report an illustrative case—additionally noteworthy because the patient had a malignant tumor that to our knowledge has not previously been reported in association with PFHA—and review the salient features of the disease.

REPORT OF A CASE

A 13-year-old girl had experienced, at 4 years of age, right facial hemiatrophy that became progressively more severe. At 5 years, she had received a graft of a portion of rib to the right maxillary area, and at 6 years, she received a silicone elastomer implant to the right cheek. The implant was subsequently removed because of chronic local infection. By 7 years of age, the atrophy had become static. Figure 1 shows her appearance at age 12.

At 12 years of age, the patient began to complain of gradually increasing pain in the left thigh. Roentgenograms showed a mottled, lytic lesion of the left ischium, and biopsy specimens from the lesion revealed Ewing's sarcoma. Chest and skeletal roentgenograms and a bone scan showed no evidence of metastatic disease. Treatment was started with vincristine sulfate and cyclophosphamide in accordance with regimen 3 of the Intergroup Ewing's Sarcoma Study.[5] One month later, she experienced a generalized seizure, followed immediately by severe pain in the left hip. The seizure was considered a complication of vincristine therapy, and roentgenograms of the hip showed a pathologic fracture of the left acetabulum with protrusion of the femur into the pelvic aperture. Open surgical reduction was carried out. During the next four months, she was kept in a spica cast and received both radiotherapy to the pelvis (5,500 rads) and prophylactic pulmonary radiation (1,500 rads).

Two months later, the patient was hospitalized again because of severe back pain that developed immediately after an auditory hallucination and a second major motor seizure. Careful questioning disclosed that since her first seizure she had been experiencing frequent isolated auditory hallucinations in the form of spoken voices of family members and telephone-ringing sounds. On examination, she appeared cachectic and was comfortable only in the supine position. Marked alopecia was present. The right side of her face below the orbit, and the adjacent subcutaneous tissues of the neck, were atrophied and distorted. The involved facial skin had areas of both hypopigmentation and hyperpigmentation. The left side of the face and neck appeared normal. Flexion of the left hip was limited, and there was marked tenderness to palpation over the lumbar spine. The deep tendon reflexes were diminished, but no other neurologic abnormalities were found.

Facial roentgenograms showed, on the right, absence of the zygoma and hypoplasia of the maxilla and mandible. The mandible was rotated superiorly and laterally, and the condylar process was atretic (Fig 2). Roentgenograms showed generalized osteoporosis, pulmonary hilar adenopathy suggestive of metastatic disease, and a compression fracture of the body of the fourth lumbar vertebra. Since a bone scan at that time was normal, the fracture was attributed to osteoporosis. An EEG and brain scan were normal. A presumptive diagnosis of temporal lobe epilepsy as a

complication of PFHA was made, and the patient was discharged on a regimen of rest, phenobarbital, and meperidine hydrochloride.

Five weeks later, roentgenograms showed that the patient had bilateral femoral metastases as well as enlargement of the previously suspected pulmonary metastases. Her family and physicians agreed that further chemotherapy should not be undertaken. The patient died at home nine months after her tumor had been diagnosed. Permission for an autopsy was not given.

COMMENT

In the present case, the history of progressively developing facial hemiatrophy is similar to that in cases reported in the surgical literature.[6,7] In addition, the present case illustrates a complication, temporal lobe epilepsy, the accurate diagnosis of which may depend on the physician's awareness of its association with this disease. Since a description of PFHA cannot be found in standard textbooks of pediatrics, neurology, or pathology, or in the general pediatric literature, a review of its features for pediatricians and others caring for children appears in order.

The disease consists of idiopathic, acquired, unilateral atrophy of the face, variably involving skin, fat, connective tissue, muscle, and bone. Occasionally, the atrophy extends to the opposite side of the face or to the ipsilateral extremities, and a variety of clinical patterns have been described.[6-8] A distinctive histologic diagnosis of PFHA is not possible in the absence of the clinical pattern, since scleroderma similarly may be characterized by atrophy of both dermis and epidermis, flattening or absence of rete pegs, inflammatory changes, and excessive collagen formation.[9,10]

Generally, PFHA begins during the first or second decade; and among reported cases, female patients predominate slightly.[6] The disease has been described in blacks,[4] whites,[8] and orientals.[11] No genetic predisposition is apparent, although there have been a few reports of familial occurrence.[6,12] The right and left sides of the face are involved equally often.[6,7]

Many hypotheses have been advanced concerning the cause of PFHA. Local trauma and infection have been incriminated as precipitating events, but neither convincingly.[7] Wartenberg considered PFHA an heredodegenerative disease,[8] while Moss and Crikelair[13] produced PFHA in rats by performing unilateral cervical sympathectomies. For the present, the cause of PFHA in humans must be considered unknown.

Clinically, the atrophic process in PFHA usually begins with a focal pigmentary change or a gradual

"sinking-in" of subcutaneous tissue in the paramedian area of the face. The disease progresses over periods ranging from several weeks to a decade or longer before eventually becoming static. Characteristic is a sharp, vertical delineation between the two sides of the face, termed "coup de sabre" (saber stroke). The degree of deformity varies widely. More severe outcomes have been thought to develop in patients whose atrophy starts before facial bone growth has been completed.[6,7]

The complications of PFHA are principally ocular and neurologic. Ocular complications occur in more than 10% of patients, and include enophthalmos, extraocular muscle weakness, iridocyclitis, and refractive changes.[3,7,12,14] Neurologic complications include Horner's syndrome, trigeminal neuralgia, migraine, and epilepsy, especially Jacksonian motor and sensory types.[8-15] Epilepsy characteristically occurs late in the course and is associated with variable EEG findings.[11] To our knowledge, the development of a malignant tumor in a child with PFHA has not been described heretofore; for this reason, no inherent relationship can be inferred in the present case between the Ewing's sarcoma and the PFHA.

The differential diagnosis of PFHA includes congenital abnormalities, posttraumatic and postsurgical atrophy, subcutaneous fat necrosis, partial lipodystrophy, and musculocutaneous atrophy secondary to cranial nerve paralysis.[9] Crikelair et al[16] have attempted to discriminate among types of facial hemiatrophy on the basis of cephalometric measurements.[16] For the clinician, perhaps the most difficult diagnostic task is to differentiate PFHA from morphea, or localized scleroderma. The clinical course may clarify the diagnosis, since PFHA eventually becomes static. However, some authors believe that scleroderma and PFHA may be variations of a single disease process.[7,8]

The deformity produced by PFHA is often severe and psychologically trying. Dimethylpolysiloxane fluid (liquid silicone) injected subcutaneously may be used to correct small defects, but its use has been associated with high rates of infection and extrusion.[17] More recently, techniques using bone and soft-tissue grafts have allowed more successful reconstructive efforts.

Plasma Adrenocorticotrophic Hormone in Congenital Adrenal Hyperplasia

Importance in Long-term Management

Stephen LaFranchi, MD

• **In a prospective study, assays of plasma adrenocorticotrophic hormone (ACTH) were compared with established criteria to evaluate the determination's usefulness in monitoring the control of congenital adrenal hyperplasia (CAH). In 22 infants and children with 21-hydroxylase deficiency, the plasma ACTH value correctly identified the status of control in 51 of 73 (70%) patient visits. Plasma ACTH concentrations were significantly higher in patients whose conditions were out of control when compared with patients whose conditions were under control, although there was an overlap between the two groups. Plasma ACTH concentrations were significantly higher in patients with sodium-losing CAH than in patients with non-sodium-losing CAH. These findings support the concepts that patients with the sodium-losing condition have a more severe enzyme deficiency and that ACTH stimualtion may be affected by sodium balance. Although plasma ACTH determinations are a useful adjunct in the long-term management of CAH, they cannot be relied on as the sole criterion of control.**

(*Am J Dis Child* 134:1068-1072, 1980)

In the most common type of congenital adrenal hyperplasia (CAH), a deficiency of the enzyme 21-hydroxylase results in decreased cortisol production, that reduces negative feedback on the pituitary gland, leading to increased production of adrenocorticotrophic hormone (ACTH). Previous reports have documented increased plasma ACTH concentrations in both untreated and treated patients with CAH.[1-6]

In the treatment of CAH, the appropriate dose of glucocorticoids is based on evaluation of traditional criteria, including growth velocity, presence or absence of virilizing signs or cushingoid changes, rate of skeletal maturation, and 24-hour urinary 17-ketosteroid (17-KS) and pregnanetriol (PT) excretion.[7] Serum 17-α-hydroxyprogesterone (17-OHP), although it is the best diagnostic test, cannot be relied on alone to determine adequacy of control.[8] More recently, the usefulness of plasma renin activity has been reported.[5] Despite careful management with established criteria, a proportion of infants and adolescents still have growth problems, inappropriate or early virilization, irregular menses, and infertility.[9-13] Also, 24-hour urine collections in infants and children are difficult to obtain and can be inaccurate.

Since suppression of plasma ACTH into the normal range may represent the most sensitive end point of optimal glucocorticoid therapy, a study was undertaken to assess the usefulness of plasma ACTH determinations in monitoring long-term control of 22 infants and children with CAH.

METHODS

The study population of 22 patients represented all infants and children with CAH followed up at the University of Oregon Health Sciences Center, Portland. All 22 had 21-hydroxylase deficiency; 16 had sodium-losing CAH (12 boys and four girls) and six had non-sodium-losing CAH (two boys, and four girls). The patients ranged in age from 2 weeks to 16½ years and were followed up for a mean of 18 months (range, three to 27 months) during the study. Three of the patients, two infants with sodium-losing CAH and one 6½-year-old girl with non-sodium-losing CAH were studied before and after treatment.

Plasma ACTH was determined by the radioimmunoassay method of Rees et al.[14] The ACTH assay was regularly sensitive to concentrations of 20 pg/mL, with intra-assay and interassay coefficients of variation of 2.2% and 15.2%, respectively. In a group of control subjects, the mean plasma ACTH value was 54 pg/mL at 8 AM and 29 pg/mL at 4 PM. Urinary 17-KS were assayed by the method of Drekter et al[15] and PT was assayed by the method of Cox.[16] Serum 17-OHP values were determined by radioimmunoassay.[17] Bone age was determined according to the standards of Gruelich and Pyle.[18] Statistical comparisons were performed using the Student's *t* test.

The patients were evaluated at three- to six-month intervals. Plasma samples for ACTH were routinely obtained between 9 and 11 AM. The 24-hour urine specimens were usually collected the previous day, although occasionally a period of one to two weeks existed between urine collection and plasma sampling. Adequacy of glucocorticoid dosage was assessed by the following criteria: (1) growth velocity, (2) bone age advancement, (3) 24-hour urinary 17-KS, and (4) 24-hour urinary PT. The assessment of whether conditions were being controlled or out of control was based on all of the above criteria. In controlled conditions, growth velocity or bone age advancement was within 2 SDs of the mean for age, whereas in uncontrolled conditions, these values were greater than 2 SDs above mean; 24-hour urinary 17-KS and PT were under control if the values were within the normal range for age, whereas they were out of control if abnormally elevated for age. When all four criteria or three of the four criteria were in agreement, the patient's condition was assessed as being in control or out of control, as indicated. When two of the criteria disagreed with

the other two so that an assessment of control was not definite, the plasma ACTH value obtained at this visit was not used for data analysis.

Treatment comprised cortisone acetate or hydrocortisone, approximately 25 mg/sq m/day, with one third of the dose administered in the morning and two thirds at bedtime. In addition, the patients with sodium-losing CAH received fludrocortisone acetate, 0.05 to 0.15 mg/day. Individual adjustments in glucocorticoid dosage were made based on results of the above studies.

• RESULTS

The results of plasma ACTH assays in the 22 infants and children with CAH are presented in Fig 1. Plasma ACTH concentrations ranged from 10 to 2,218 pg/mL (normal, 10 to 100 pg/mL) in these children receiving treatment. When patients' conditions were judged to be controlled by previously established criteria, the plasma ACTH value was normal in 27 of 34 samplings. When patients' conditions were judged to be out of control, the plasma ACTH value was abnormally elevated in 24 of 39 measurements. Plasma ACTH concentrations (mean ± SEM) were significantly higher in out-of-control conditions (334 ± 82 pg/mL) than in controlled conditions (87 ± 15 pg/mL) ($P < .01$). Patients with sodium-losing CAH whose conditions were out of control had significantly higher plasma ACTH concentrations (372 ± 95 pg/mL) than those whose conditions were in control (83 ± 15 pg/mL) ($P < .01$). However, the plasma ACTH concentration was not significantly different in patients with non-sodium-losing CAH whose conditions were out of control (124 ± 50 pg/mL) than in those whose conditions were in control (122 ± 66 pg/mL). Also, the plasma ACTH value was significantly higher ($P < .02$) in all samples from patients with sodium-losing CAH (234 ± 53 pg/mL) when compared with all samples from patients with non-sodium-losing CAH (123 ± 38 pg/mL). When the plasma ACTH value was plotted against the corresponding 24-hour urinary 17-KS or PT concentrations, no significant correlations were obtained.

The results of plasma ACTH, 24-hour urinary 17-KS and PT, and serum 17-OHP in three patients at the time of diagnosis, before treatment and after treatment, are shown in the Table. In two infants with newly diagnosed sodium-losing CAH, the elevated plasma ACTH value was suppressed into the normal range in nine days and two months, respectively. In the 6½-year-old girl with non-sodium-losing CAH, two plasma ACTH determinations prior to treatment did not show any diurnal variation, and they

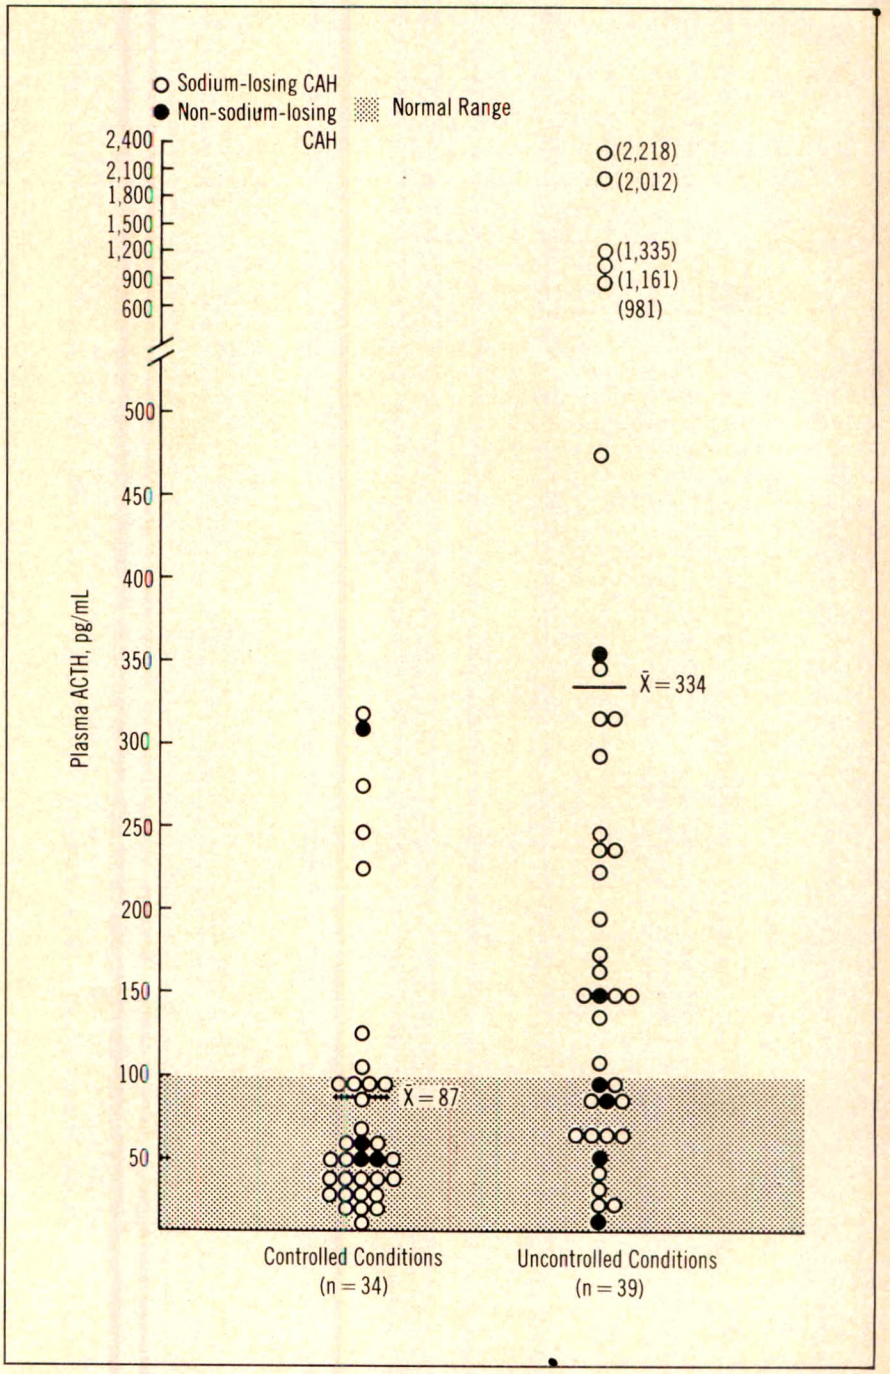

Fig 1.—Plasma adrenocorticotrophic hormone (ACTH) concentrations in controlled and uncontrolled conditions. In controlled conditions, growth velocity and bone age advancement were within 2 SDs of mean for age and 24-hour urinary 17-ketosteroid (17-KS) and pregnanetriol (PT) values were normal for age. Conditions were out of control if growth velocity and bone age advancement were beyond 2 SDs of mean and urinary 17-KS and PT were abnormally elevated for age. CAH indicates congenital adrenal hyperplasia.

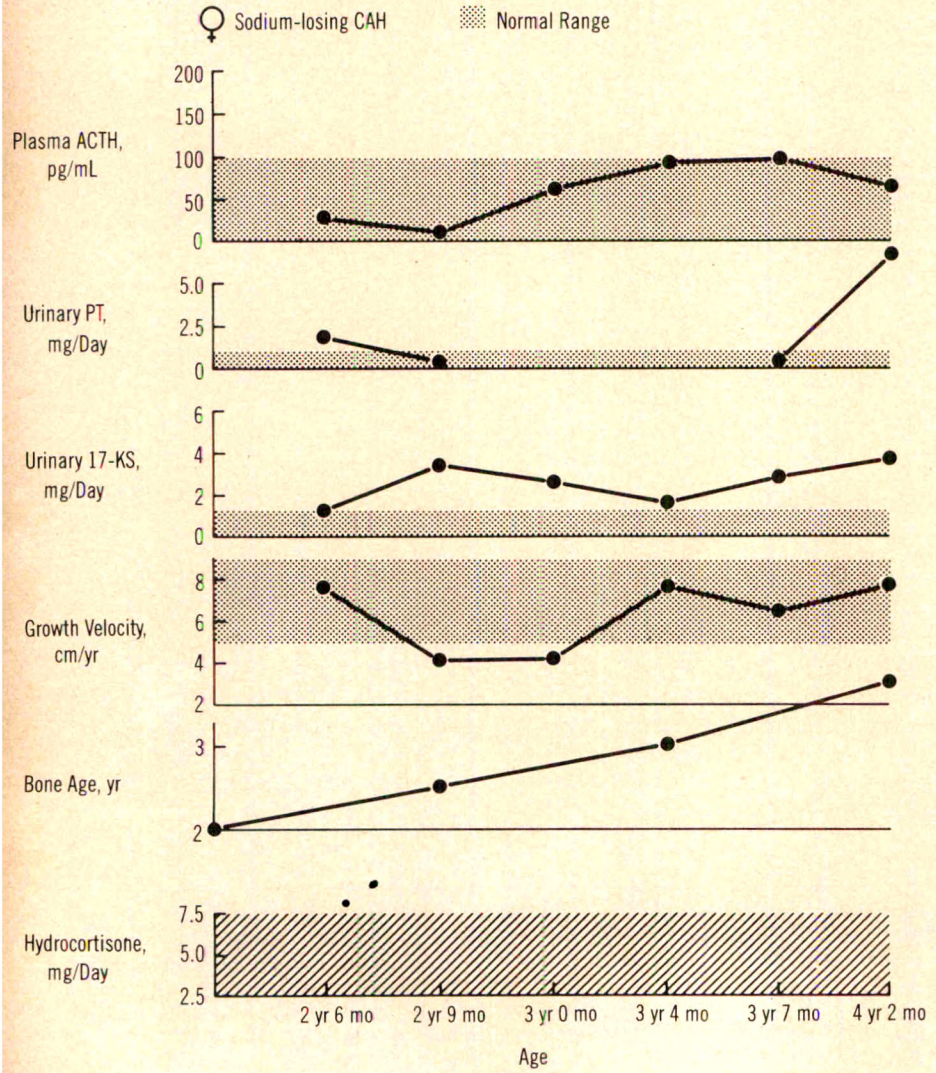
Fig 2.—Results of determinations of plasma adrenocorticotrophic hormone (ACTH), 24-hour urinary 17-ketosteroid (17-KS) and pregnanetriol (PT), growth velocity, and bone age in girl with treated sodium-losing congential adrenal hyperplasia (CAH) from chronological age 2 years 3 months to 4 years 2 months. Shaded area for growth velocity includes mean ± 2 SDs.



were in the normal range. At 7 AM, the serum cortisol value was 10 μg/dL at the time when the plasma ACTH value was 74 pg/mL. The plasma ACTH value showed little change after three days of dexamethasone treatment, 2 mg daily (65 pg/mL).

Some of the difficulty in determining the status of control and the usefulness of plasma ACTH concentrations is illustrated by the patient data in Fig 2 and 3. In Fig 2, plasma ACTH values, 24-hour urinary PT and 17-KS excretion, growth velocity, bone age, and hydrocortisone dosage are shown for a girl with sodium-losing CAH from the ages of 2½ to 4 years 2 months. Between 2½ years and 3 years 7 months, growth velocity, bone age maturation, and 24-hour urinary PT excretion were usually normal, the 24-hour urinary 17-KS values were mildly elevated, and the plasma ACTH concentrations ranged from 21 to 100 pg/mL. At 4 years 2 months, the growth velocity was 7.6 cm/yr and the bone age had advanced from 3 years to 3 years 8 months (at chronological ages 3 years 4 months to 4 years 2 months), yet the 24-hour urinary 17-KS concentration was 3.8 mg and the PT concentration was 5.8 mg (both of these values are elevated). Thus, two criteria indicated good control while two criteria indicated poor control, and the importance of the plasma ACTH concentration of 63 pg/mL could not be determined.

In Fig 3, similar studies are presented for a boy with sodium-losing CAH from the ages of 4 years 5

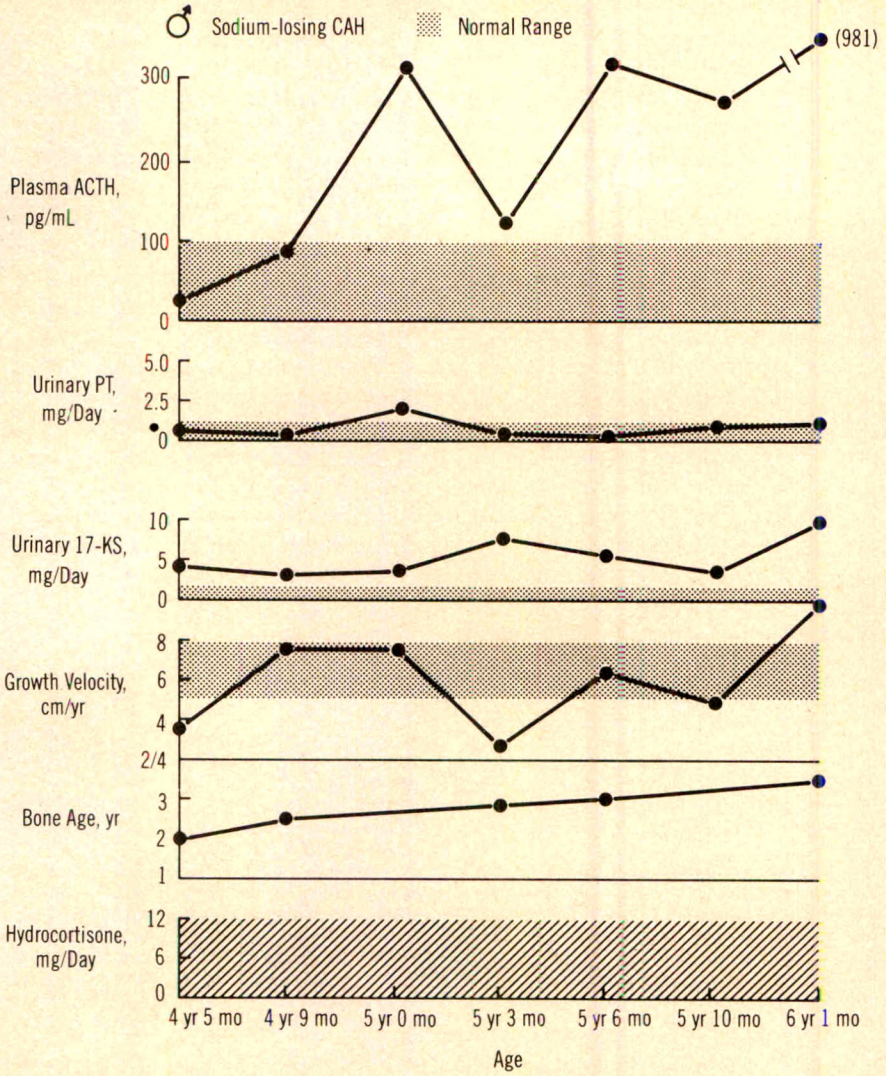


Fig 3.—Results of determinations of plasma adrenocorticotrophic hormone (ACTH), 24-hour urinary 17-ketosteroid (17-KS) and pregnanetriol (PT), growth velocity, and bone age in boy with treated sodium-losing congenital adrenal hyperplasia (CAH) from chronological age 4 years 5 months to 6 years 1 month. Shaded area for growth velocity includes mean ± 2 SDs.

months to 6 years 1 month. The patient's condition was judged to be in control at 4 years 5 months (plasma ACTH value, 27 pg/mL) and at 4 years 9 months (plasma ACTH value, 87 pg/mL), whereas at 5 years his condition was judged to be out of control (plasma ACTH value, 319 pg/mL). At 5 years 3 months, the growth velocity fell to 2.4 cm/yr, the bone age was 2 years 8 months, representing an increase of 4 months during the last half year, and the 24-hour urinary PT concentration was 0.4 ng, yet the 24-hour urinary 17-KS value was 7.6 mg. Since three of four values were normal or suppressed, the patient's condition was judged to be in control; the plasma ACTH value was mildly elevated at 126 pg/mL. At 5½ years and at 5 years 10 months, the patient's condition was judged to be in control on the basis of three of four criteria, yet the plasma ACTH value was even more elevated at 317 pg/mL and 273 pg/mL, respectively. Finally, at 6 years 1 month, the patient's condition was judged to be out of control: the growth rate was 10 cm/yr, he had elevated urinary 17-KS and PT values, and the plasma ACTH level was elevated to 981 pg/mL.

COMMENT

When plasma ACTH measurements were obtained along with other traditional criteria to evaluate control in infants and children with CAH, it correctly identified the status of control in 70% (51/73) of patient visits. Although plasma ACTH concentrations were significantly higher in patients whose conditions were judged to be out of control than in patients with controlled conditions, there was an overlap in values between these groups. As a whole, plasma ACTH concentrations were also significantly higher in samples from patients with sodium-losing CAH than from patients with non-sodium-losing CAH, and the highest ACTH levels were seen in patients with sodium-losing CAH. This finding is similar to that of Rösler et al[5] and lends support to their notion that the degree of ACTH stimulation is proportional to the degree of enzymatic deficiency; patients with sodium-losing CAH appear to have a greater deficiency of 21-hydroxylase.

As evidenced by Fig 1 through 3, the plasma ACTH value may be normal when other criteria indicate that the condition is out of control, or it may be elevated when the condition seems to be controlled. Although the explanation of these aberrant situations is not known, there are several possibilities. Some patients whose conditions were in good control may have neglected to take their morning dose of glucocorticoid. The lack of medication for 12 to 14 hours may have resulted in an elevated plasma ACTH value. In patients with treated CAH, Pham-Hun-Trung et al[6] found plasma ACTH concentrations of up to 475 pg/mL 12 to 14 hours after the last dose of glucocorticoid. Plasma ACTH values should be determined two to four hours after the morning dose of glucocorticoid. It is also possible that episodic secretion of plasma ACTH produced some variability in the results. Fukushima et al[19] reported that plasma ACTH values, when sampled every 20 minutes, varied through a tenfold range (12 to 120 pg/mL) between 12 noon and 4 PM in patients with untreated 21-hydroxylase deficiency. A more important explanation when conditions seem to be in good control but the plasma ACTH concentration is elevated may be subclinical

sodium wasting. Rösler et al[5] reported that a low sodium diet produced excessively high levels of plasma renin activity in children with CAH. They found that the degree of ACTH stimulation significantly correlated with the levels of plasma renin activity and was proportional to the degree of sodium loss. Although none of our patients had clinical manifestations of sodium loss or hypovolemia, this may explain seemingly paradoxically elevated plasma ACTH concentrations. These situations would indicate a need to determine plasma renin activity and adjust mineralocorticoid therapy if necessary.

As seen in case 1 in the Table, the pituitary-adrenal axis would appear to respond rapidly to glucocorticoid administration. The plasma ACTH value was normal nine days after treatment was started, and perhaps this normalization would have been seen sooner had it been evaluated. It is unclear why the initial plasma ACTH value in patient 3 (Table), a non-sodium-loser, was not elevated. As previously stated, plasma ACTH concentrations are lower in patients with non-sodium-losing CAH. Fukushima et al[19] have reported normal plasma ACTH concentrations in untreated patients with non-sodium-losing CAH. The patients with non-sodium-losing CAH probably have a milder, partial enzymatic deficiency. Once the adrenal glands hypertrophy, these patients are able to secrete adequate amounts of cortisol under basal conditions, as was the case in patient 3. It may be that the initially high ACTH secretion is inhibited as more cortisol is produced by the hypertrophied adrenal as pituitary-adrenal homeostasis occurs. Although a normal amount of ACTH would be sufficient to stimulate secretion of physiologic amounts of cortisol in these situations of mild enzymatic deficiencies, this would not be the case with the sodium-losing condition, which represents a more severe enzyme deficiency.

From this study it can be concluded that plasma ACTH is a useful adjunct in long-term management of CAH. However, it cannot be relied on as the sole criterion of control, and established studies should continue to be the main criteria of control.

Monte Greer, MD, performed the plasma ACTH measurements.

Review Article

Diets for Children and Adolescents That Meet the Dietary Goals

Johanna Dwyer, DSc

• **The parents of many elementary and secondary schoolchildren ask pediatricians for advice on how to feed diets that are in line with the US *Dietary Goals* or the *Dietary Guidelines for Americans.* This article outlines an approach for planning diets that fit these recommendations while also assuring that intakes approximate the recommended dietary allowances and the estimated safe and adequate intakes of nutrients provided by the Food and Nutrition Board, National Research Council.**

(*Am J Dis Child* 134:1073-1080, 1980)

In the past decade, American parents became increasingly concerned about weight control, appropriate levels of fat, cholesterol, sugar, protein, vitamins, and minerals in family diets, and other issues related to health promotion and disease prevention.[1-3] Following the publication of recommendations directed to the lay public by various government bodies during the past three years, interest in these topics increased. All of these publications include advice about avoiding imbalance or excesses with respect to intakes of nutrients,[4-7] whereas previous dietary guidance only dealt with the issues of getting enough of the essential nutrients and avoiding obesity.[8-11] The Dietary Goals for the United States, issued by the Senate Select Committee on Nutrition and Human Needs in 1977, recommends specific dietary levels for the type and amount of fat, protein, and carbohydrate and amount of cholesterol and sodium to be consumed, as well as an exhortation to achieve energy balance.[4] Publications of the executive agencies of government, including the Surgeon General's report,[5,12] the USDA's new food guide,[6] and the joint USDA-Health, Education, and Welfare *Dietary Guidelines for Americans*,[7] provide more general guidance about these same constituents in the diet and sometimes include other information on health promotion. But few of them provide specific assistance in planning such diets for children.[12-14] Parents, like Jason and his Argonauts, are left without precise navigational advice to chart a course between the Scylla of insufficiency and the Charibdis of dietary excess for their offspring. As a result, they frequently turn to their pediatricians for dietary guidance.

The *Dietary Goals*, and to a lesser extent the subsequent publications that addressed these issues, gave rise to vigorous debate in professional circles.[15-28] Today, some pediatricians are urging their patients to follow some or all of the "goals," while others remain skeptical. Benefits deriving from following the guidelines are difficult to estimate since the efficacy of the measures vary, and are further influenced in a favorable manner by the adoption of other preventively oriented behaviors.[24] Similarly, the calculus of risks is not entirely clear for children and adolescents, although for adults, they pose little risk and some promise of benefit.[18] If the *Dietary Goals* were taken as the only source of dietary guidance, shortfalls in intakes of some protective micronutrients such as vitamins and minerals might arise that would pose risks to child health.[25] In any event, there is little doubt that diets for children and adolescents need to be chosen with care. When the *Dietary Goals* or similar guides are used, even more attention to planning is warranted, since additional constraints are placed on the choice of foods.

Until now, few dietary patterns have been published that are specifi-

cally designed for children and assure sufficiency of micronutrient intakes while also achieving the desiderata for type and amount of fat, carbohydrate, and amounts of cholesterol, sodium, and energy that are outlined in the *Dietary Goals*.

A first approximation toward such patterns is presented herein. For pediatricians who have decided that such regimens are suitable for children of primary school age or older, this article offers practical advice about how to proceed in helping parents plan such diets in line with other relevant information about appropriate dietary intakes of children. For pediatricians who are unconvinced about the merits of such patterns, information on present intakes of children and adolescents is summarized, and suggestions about child diet and life-style practices are provided.

PRESENT DIETS OF CHILDREN AND ADOLESCENTS

Data on the usual dietary intakes and nutritional status of children and adolescents collected during the Ten-State Nutrition Survey[29] and the Health and Nutrition Examination Survey (HANES)[30] revealed that shortfalls in intakes of certain nutrients, as well as related indices of health status, did exist. In the ten-state survey, which focused on those in low income groups, primary schoolchildren in the poverty groups surveyed were judged to have a medium to high prevalence of deficient values for iron, and retarded growth and development. In addition, black and Spanish-American children had a medium to high prevalence of low serum riboflavin values, and Spanish-American children also exhibited similar indices for vitamin A nutriture. The HANES survey, which included all income groups, found that while mean micronutrient intakes were generally satisfactory, 30% or more of the primary schoolchildren had intakes below the levels specified in the recommended dietary allowances for iron, vitamin A, and ascorbic acid as being appropriate. Among adolescents, those interviewed in the ten-state survey showed a medium to high prevalence of nutrition problems related to iron. Subgroups showed similar shortfalls of riboflavin (blacks, Spanish Americans), and indices indicative of obesity (white male children). Adolescent's micronutrient intakes in the HANES survey generally approximated the recommended allowances, but 30% or more of the adolescents had iron, vitamin A, and ascorbic acid intakes below the standard; and girls aged 12 to 17 also exhibited similar shortfalls for protein and calcium. A substantial proportion of all children had particularly low energy intakes, although overt malnutrition was rare and obesity quite common, suggesting that energy outputs were lower, and/or energy

Table 1.—Intakes of Children Aged 6 to 11 Years in Health and Nutrition Examination Survey

	Food Group*				
	Milk	Meat	Breads and Cereals	Fruits and Vegetables	Fats, Sweets, or Alcohol
% of total calories	23	15	26	11	23
Provides 20% or more of total intakes of:

Ascorbic acid				X	

*Food group mentioned provides 20% or more of the constituent in question.

intakes were higher than recommendations.[31,32] Finally, preliminary estimates from the HANES data indicate that the intakes of both children and adolescents of these ages are higher in total fat, saturated fat, added sugar, protein, and sodium than the levels specified in the *Dietary Goals*.[33] We can conclude that the present dietary patterns of many children and adolescents deviate significantly from whatever recommendations one wishes to use.

Tables 1 and 2 present the dietary intakes of children 6 to 11 and adolescents 12 to 17 years of age from the HANES survey data by groups of foods consumed. The proportion of total calories from each food group and the contributions that exceed 20% of total intakes for each of the other nutrients specified are listed. A glance at the tables will illustrate the reason why rather specific information on food choices must be provided if one is to devise diets that meet the dietary goals and fulfill recommended allowances. Note that the "milk" and "meat" groups that have traditionally been emphasized as being the mainstays of children's diets because they make generous contributions of protective nutrients are "problem" foods from the standpoint of their rather large contributions to total fat, saturated fat, and cholesterol. Another old favorite of nutrition educators and pediatricians, the bread and cereal group, makes substantial contributions to sodium intakes and provides many of the protective nutrients. The fruit and vegetable group provides relatively little of any of these substances, but is a good source of vitamin A, some of the B vitamins, folic acid, and ascorbic acid. The final food group in these tables, eg, the "fats, sweets, alcohol" group, provides a good deal of fat, sugar, and energy, but contributes almost none of the protective nutrients.

Table 3.—Suggestions to Parents for Cutting Back on Fat in Family Diets

1. Cut down on fatty meats such as regular ground beef, corned beef, spareribs, sausage, heavily marbled cuts of beef such as prime ribs and steak. Leaner cuts of red meat include flank, round, and rump (especially choice or good rather than prime grades), lamb legs and loin, lean ham and lean pork loin, picnic and Boston butt hams.
2. Broil or bake rather than fry. Trim meat of fat before eating.
3. Substitute lower fat meats such as veal and poultry in place of fatty meats. Use fish and legumes more frequently.
4. Substitute low-fat or nonfat skim milk for whole milk, and low-fat for high-fat dairy products. This implies reduction in the use of whole milk and milk products such as most cheeses and ice cream, and substitution of lower fat products such as skim milk, uncreamed cottage cheese, low-fat yogurt and low-fat cheeses.
5. Instead of table fats like butter, use polyunsaturated "soft" margarines, which are lower in saturated fat.
6. Decrease consumption of hidden sources of fats present in fried foods, foods served with heavy sauces or gravies, baked goods such as pastries, chocolate, nuts, and "regular" peanut butter (natural peanut butters are somewhat lower in fat and sugar).

Table 4.—Suggestions to Parents for Cutting Back on Sugar in Family Diets

1. Keep the sugar bowl off the table.
2. Decrease candy, pie, pastry, cake, cookie, and sweet roll consumption. Save them for weekends.
3. Avoid desserts or between-meal snacks of sweet, sticky foods.
4. Avoid regular soft drinks, punches, fruit drinks, and ades high in sugar. Fruit juices contain less sugar.
5. Buy fruit canned in its own juice or in light instead of heavy syrup (which is also high in sugar), or eat fruits raw.
6. Check ingredient labels. Avoid those that have sugar (or words that mean sugar, such as glucose, sucrose, fructose, corn syrup, or sweeteners) high on the ingredient list.
7. Avoid presweetened products.

RATIONALE

The rationale of the menu planning approach described herein rests on several assumptions that need to be understood by parents if they are to use these diets for their children. First, the most appropriate way to assure sufficiency while avoiding an excess of nutrients or energy is to alter the type and amounts of foods individuals in these age groups commonly eat. The use of vitamin or mineral supplements is not regarded as necessary if the steps outlined are followed. However, children eat most of their food at home and copy the habits of their parents; and it is unreasonable to expect that children will follow dietary patterns that are radically different from those of their families. Therefore, changes in food availability in the home and eating habits of the entire family, and not only those of the child, will be necessary. General suggestions are provided in Tables 3 to 5, and the menus provided are suitable for adults as well as children with minor modifications.

Second, eating should be pleasant. Children have a right to a certain amount of independence in their own food choices. Diets should be flexible enough to permit individual choice and variety, and be adaptable to the child's individual social life.

Third, the menus presented herein are suitable only for well children over 5 years of age or for adults. They provide less calcium, phosphorus, iron, and zinc than recommended levels for younger children. Nor are they suitable as substitutes for therapeutic diets. Expert assistance from a physician and a dietitian is called for if diets for children or adolescents who fall into these categories are to be developed.

Fourth, health promotion measures other than diet also are seen as important. Diet is only one of the health promotion and disease prevention measures appropriate for children and adolescents. Adequate exercise, good sense in using food for rewards or other emotional purposes, oral hygiene, and regular health care are also indicated. It is within this general context that nutrition education should be provided.

Fifth, vegetarian diets are not called for. Some parents and physicians have become confused and assume that since the micronutrient levels suggested are more similar to vegetarian patterns than are current American diets that a switch to vegetarianism is necessary. This is actually not the case—modifications can be achieved simply by moderation in the use of some types of animal foods. Actually, vegetarian patterns usually

Table 5.—Suggestions to Parents for Cutting Back on Salt in Family Diets

1. Keep the salt shaker off the table.
2. Cut back on salting foods during cooking; use lemon juice, herbs, and spices instead.
3. Cut down on salty snacks such as potato chips, pretzels, salted popcorn, salted nuts, and crackers.
4. Avoid salty and smoked meats and fish like bologna, corned beef, chipped beef, frankfurters, ham, luncheon meats, salt pork, sausage, smoked tongue, salt or dried cod, herring, and anchovies.
5. Cut down on other high-salt foods such as processed cheese, aged cheese, foods prepared in brine (pickles, olives, sauerkraut), canned and instant soups or bouillons, oriental noodles with soup, garnishes and condiments like soy sauce, Worcestershire sauce, mustard, and barbecue sauce.
6. Check food labels and avoid foods in which sodium or salt is high on the ingredient list.

provide less animal protein, sugar, total fat, saturated fat, sodium, and cholesterol than do the dietary goals.[34-36] Some of the more restrictive vegetarian regimens include additional constraints on the use of foods that are considered to be "processed" or "nonorganic" (such as some fortified and enriched foods), and disuse of vitamin and mineral supplements. Such practices increase the difficulties of achieving sufficiency for some micronutrients. Those who wish to counsel patients on following vegetarian diets are referred to several excellent references on planning of vegetarian regimens.[37-39]

SPECIFIC RECOMMENDATIONS

Diet Strategy

In order to help parents plan diets that achieve these objectives, this five-point strategy is helpful.

1. *Decrease choices of foods such as fats, sugars, and sweets that contribute a great deal of energy, fat, or sugar, and little else. Substitute foods that are more balanced in their contributions.*

In making suggestions to parents, foods that are high in energy and low in protective nutrients are the first to tackle and cut back on. There are three reasons for "going easy" on choices in this group. First, this group constitutes almost a quarter of overall energy intakes in children's diets. Second, most of the commonly eaten items in this group provide disproportionately high amounts of energy for their contributions of protective nutrients. If energy intakes are excessive, cutbacks on energy contributions from these sources will do little violence to overall diet quality and may, in fact, help to improve it. Third, this group also contributes a substantial proportion of the total fat and sugar (and especially the sticky, sugary foods eaten between meals that particularly increase risks of dental caries development) in children's diets. Dietary alterations specified in Tables 3 and 4 can help in achieving these objectives.

Theoretically, it might seem sensible to simply tell parents to eliminate these items entirely from their diets and those of their children. But such a strategy is doomed to failure. These foods are widely available and highly preferred by everyone in the family. They are often used for emotional purposes since they are regarded as "fun" foods, treats, or rewards. Therefore, the proper strategy is to decrease their intake but not eliminate them, while providing acceptable substitutes.

If children take lunch or a snack to school, parents should pack suitable snack and dessert items that are lower in calories and fermentable carbohydrates, using the lists given in Table 6. Children need a good deal of assistance in making wise choices of snacks, "treats," or desserts eaten outside of the home, since sugary, sticky candies and confections are popular. Suggestions given in Tables 4 and 6 may also be helpful for this.

2. *Increase consumption of fruits and vegetables, breads and cereals, dried beans or peas, and starchy vegetables.*

• **Fruits and Vegetables.**—Taken together, fruits and vegetables, including juices, make only minor contributions to total calories. As a group, they are low in calories and high in protective nutrients such as ascorbic acid, vitamin A value, and folic acid, provide a good deal of dietary fiber, and contribute less than their proportion of calories for all of the food constituents mentioned in the guidelines except for sugar, which appears primarily as a natural constituent in some fresh fruits. Starchy vegetables such as potatoes and corn are also relatively low in calories and are filling.

Fruits are highly acceptable substitutes for sweets and the usual desserts and snacks, which are higher in sugar and calories. Their consumption should be stressed—at least five or more servings a day. At least one good ascorbic acid source and a dark green or deep yellow vegetable for vitamin A should be included each day among selections from this group.

• **Whole Grain, Enriched or Fortified Cereals, and Bread.**—In their totality, this group constitutes about a quarter of total calories. With the exception of sodium, they make only minor contributions of constituents for which greater moderation is called for (fat, saturated fat, cholesterol, and sugar), while providing relatively large amounts of the protective nutrients (iron, protein, several of the B vitamins, and complex carbohydrates). Whole grain products are also rich in magnesium, trace elements, folic acid, and fiber. Fortified cereal products such as breakfast cereals usually have increased levels of iron and may also contain vitamins A, B_{12}, C, and D, not usually present in cereals. Enriched products provide amounts of iron, thiamin, riboflavin, and niacin similar to those in whole grain products. For this reason, whole grain, enriched, or fortified foods from this group should be emphasized rather than the highly refined, unfortified products.

The strategy is to increase consumption of whole grain or enriched breads, whole grain, enriched and fortified cereals (especially the unsugared varieties), and other low-fat cereal products. Some are good snack choices. The mixed protein dishes, such as casseroles, can be used as entrees, while others are good side dishes. Four to six servings of these foods a day are suggested.

• **Dried Beans, Peas, and Nuts.**—Foods such as soybeans, baked beans,

Table 6.—Snack Foods That Are More Acceptable Substitutes Than Usual Choices for Children and Adolescents

1. Fresh fruits or water-packed canned fruits.
2. Finger vegetables such as radishes, carrot sticks, celery stalks, and raw cauliflower pieces, and cherry tomatoes.
3. Fruit juices.
4. Low-fat yogurt (unsweetened).
5. Low-fat or skim milk.
6. Low-fat cheese.
7. Nuts or sunflower seeds.
8. Whole grain or enriched crackers (unsalted).
9. Unsalted popcorn or pretzels.

peanuts, lentils, and other types of dried beans and peas are high in protein, phosphorus, vitamin B_6, and magnesium, while being lower in energy and saturated fat than many animal foods that are also high in these nutrients. Therefore, their use should be encouraged.

3. *Substitute alternatives for whole fat milk products, fatty meats, and eggs that are lower in energy, lower in fat, saturated fat, cholesterol, and sodium, while keeping protective nutrient contributions of foods in these groups at a high level.*

Since these foods make major contributions of protective nutrients, the strategy in dealing with them is to exchange or substitute similar foods that have these advantages and also are lower in total fat, saturated fat, cholesterol, or sodium.

• **Whole Fat Milk Products.**—Milk and milk products provide almost a quarter of the total calories children eat. While they make substantial contributions of calcium, phosphorus, vitamins A, D, B_2, and protein, they also provide a good deal of the total fat, saturated fat, cholesterol, and sodium, as well as a fair amount of sugar in children's diets. By one simple measure, substituting vitamin D-fortified skim milk for whole milk, total fat, saturated fat, and energy can be substantially reduced while preserving intakes of the protective nutrients. This is probably the simplest single recommendation that can be given to parents. Most children are accustomed to the taste and rich mouth feel of whole milk, and so a gradual "weaning" process, rather than an out-and-out switch, is sensible. By mixing reconstituted skim milk from powder in equal proportions with whole milk, homemade 2% milk can be easily produced at a substantial savings over usual fluid milk costs. Gradually, the ratio can be increased to two parts skim to one part whole milk, and the result is a nearly skim milk with slightly more body and lower cost than store-bought skim milk. Low-fat cheeses and sherbet or ice milk instead of ice cream are also in order here. At least three servings from these foods should be included each day.

• **Fatty Meats.**—Meats contribute about an eighth of total calories and provide substantial proportions of protein, iron, niacin, and vitamins B_6 and B_{12}. However, some items, such as fatty red meats, provide relatively more total fat, saturated fat, and cholesterol than their caloric contribution. The strategy here is to emphasize more consumption of poultry, fish, shellfish, legumes (beans, peas), and nuts, which are lower in fat and cholesterol. At the same time, the use of trimmed or lower fat cuts of red meats should be encouraged.

In food preparation, a balance of about half meat and half poultry, fish, or low-fat meats can be aimed for. Broiling and baking are preferable to frying. Meats should be trimmed before eating and drippings should be discarded. At least two servings of fish, poultry, lean meat, or dried beans should be included each day.

• **Eggs.**—Eggs are good sources of protein and also provide substantial amounts of vitamin A. However, an average egg provides approximately 250 mg of cholesterol, and thus it is also a major contributor to dietary cholesterol. There is no reason to eliminate eggs from children's diets since their current intakes do not appear to be excessive.

4. *Help parents make changes that will facilitate this dietary pattern.*

Importance of Parents as Role Models.—Many parents are unaware of the great influence their own eating behavior has on that of their children. They should be encouraged to alter their own diets to serve as better role models for their children.

Altering Food Availability in the Home.—The key to modifying children's and adolescents' diets is for the shopper to buy and stock home larders with appropriate foods. Food preparation practices also need alteration, and these depend more on the parent than they do on the child. Helpful alterations include choices of lean meats, poultry, and fish; the trimming of fatty meats; draining of drippings; use of broiling and baking rather than frying; disuse of salt in food preparation and on the table; use of soft margarines or vegetable oils in cooking and as table spreads; providing easy access to fruits, vegetables, and juices for snacks and desserts.

Parental Views Should Be Publicized for Food Variety to Be Available Away From Home.—All too often, parents assume that they have no influence over what their children eat in schools, recreation centers, and so on, but in many of these settings, such as schools, means do exist whereby parents can urge that alternative choices be provided. Parents should be encouraged to become involved in advisory groups and boards that make these decisions so that school lunches and other meals children are likely to eat outside the home can be adjusted to meet children's diets.

Pack Suitable Lunches and Snacks.—Contrary to myth, children obtain many of the sugary sweets, desserts, confections, and beverages they eat in their own homes or in home-packed lunches that they take to school. Table 3 suggests some appropriate substitutes for the usual snacks and desserts that are used in many packed lunches for children.

Assist Children in Making Wise Choices When Eating Away From Home.—Parents need to teach children to make wise food choices when children are on their own. Helpful guides are available to help them do this.[6,40]

5. *Assure adequate attention to oth-*

Table 7.—Menus for Children and Adolescents That Approximate Dietary Goals

Breakfast	Lunch	Dinner	Snacks
Iron-fortified wheat cereal, 1 cup Sugar, 1 tsp Banana, 1 Milk, skim, 1 cup	Cheeseburger and bun Coleslaw, 1/2 cup French fries, 1 serving Milk, skim, 1 cup	Chicken cacciatore, 1 serving Spaghetti, 1 cup Escarole, 1/2 cup, braised Tossed salad, 1-½ cup Italian dressing, 1 Tbsp Italian bread, 2 slices Margarine, 1 tsp, soft Tangerine, 1 medium Milk, skim, 1 cup	Peanut butter–orange sandwich (2 slices whole wheat bread, orange slices, peanut butter) Milk, skim, 1 cup Soft drink, 8 oz
Orange juice, 3/4 cup Scrambled egg, 1 large Bagel, 1 Neufchatel (low-fat cream cheese), 1 Tbsp Milk, skim, 1 cup	Chicken sandwich (3 oz white meat, 1 tsp soft margarine, 1 tsp salad dressing, 2 slices whole wheat bread) Raw green pepper, 1, sliced Apple, 1 medium Milk, skim, 1 cup	Vegetable chowder, 1 serving Bean salad, 1 serving Baked fish, 1 serving Broccoli, 1/2 cup Brown rice, 1/2 cup Rye bread, 2 slices Margarine, 2 tsp, soft Honeydew melon, 1 slice Milk, skim, 1 cup	Gingerbread, 1 slice Applesauce, unsweetened, 1/2 cup, and cinnamon sandwich with 2 slices whole wheat bread 1 orange Milk, skim, 1 cup
Raisin-type English muffins, 2 Peanut butter, 2 Tbsp Cantaloupe, 1/4 medium Milk, skim, 1 cup	Pork loin, 1 large, lean only Carrots, 1/2 cup Black-eyed peas, 1/2 cup cooked Rice, 1/2 cup Sliced peaches, 1/2 cup Milk, skim, 1 cup	Flounder, 1 serving Mashed potato, 1/2 cup, with margarine Broccoli, 1/2 cup Whole wheat roll, 1 Margarine, 2 tsp, soft Low-fat plain yogurt, 1 cup Blueberries, 1/2 cup Milk, skim, 1 cup	Corn muffins, 2 average Jelly, 2 Tbsp Apple cider, 3/4 cup Raw vegetable sticks, 1/2 cup
Orange juice, 3/4 cup Banana-nut bread, 3 slices Cottage cheese, low-fat, 3/4 cup Milk, skim, 1 cup	Peanut butter and raisin sandwich Carrot, 1 large Pear, 1 large Milk, skim, 1 cup	Pot roast, lean chuck only, 4 oz Mashed potato, 3/4 cup Green beans, 1/2 cup Spinach salad, 1 cup Italian dressing, 1 Tbsp Biscuits, 2 Margarine, 2 tsp, soft Ambrosia, 1/2 cup Milk, skim, 1 cup	Chili bean dip Raw vegetable sticks, 1 cup Whole wheat crackers, 6 Apple, 1 medium Milk, skim, 1 cup with chocolate syrup, 1 Tbsp
Fresh grapefruit, 1/2 medium Shredded-wheat biscuits, 2 Sugar, 1 tsp Milk, skim, 1 cup	Turkey-ham sandwich on rye bread (2 oz turkey, 1 oz ham, and 2 slices rye bread) Margarine, 2 tsp Pear, 1 medium Milk, skim, 1 cup	Green salad, 1 cup French dressing, 2 Tbsp Chopped steak, 4 oz Acorn squash with 1 tsp brown sugar, 1/2 medium Green beans, 1/2 cup Corn bread, 1 serving Baked apple with 2 tsp brown sugar, 1 medium Milk, skim, 1 cup	Orange-pineapple juice, 3/4 cup Peanut butter sandwich (2 Tbsp peanut butter and 2 slices whole wheat bread) Milk, skim, 1 cup Celery sticks Swiss cheese cubes, 1-½ oz
Orange juice, 3/4 cup Whole wheat pancakes, 3 Maple syrup, 2 Tbsp Margarine, 2 Tbsp, soft Milk, skim, 1 cup	Beef tacos, 2 Tossed salad (lettuce, tomato, green onions, and carrots), 1-¼ cup Italian salad dressing, 1 Tbsp Milk, skim, 1 cup	Roast loin of pork, lean only, 4 oz Sweet potato, baked, 1 medium Cauliflower, 1/2 cup Biscuits, 2 Margarine, 2 Tbsp, soft Honey, 1 Tbsp Fresh fruit cup (oranges, apples, banana), 2/3 cup Milk, skim, 1 cup	Graham crackers, 4 Apple, 1 medium Lemonade, 12 oz
Orange-grapefruit juice, 3/4 cup Oatmeal with cinnamon and 2 Tbsp raisins, 1/2 cup Brown sugar, 1 tsp Milk, skim, 1 cup	Pea soup, 1 serving Chicken-salad sandwich on rye bread (2 oz chicken, 1 Tbsp celery, 1 tsp onion, 2 Tbsp mayonnaise) Tomato, 1 whole Margarine, 2 Tbsp, soft Plum, 1 Milk, skim, 1 cup	Beef with Chinese vegetables, 1-½ servings Brown rice, 1 cup Pineapple chunks, canned, 1/2 cup Milk, skim, 1 cup	Banana-nut bread, 2 slices Lemon sherbet, 1/2 cup Apple, 1 Apple crisp, 1 serving

er health-promotive life-style behaviors closely related to diet.

Encourage Vigorous Physical Activity.—Americans are among the most sedentary people in the world, and their children are no exception. There are a number of reasons for encouraging both children and their parents to lead more physically active lives, regardless of whether they are lean or fat. First, the more active the child, the more food he or she will eat and the easier it is to assure that protective nutrient needs are met. Those who eat diets providing relatively little energy, even if their weights are within normal limits, often have low intakes of iron, vitamin B_6, zinc, and magnesium. Second, it is easier to maintain normal fatness status or, if necessary, to reduce it if the child regularly engages in vigorous physical activity. Third, there is reason to suspect that, at least in adults, vigorous physical activity as well as diet and nonsmoking is associated with elevated levels of high-density lipoproteins, which may be associated with a lowered risk of coronary heart disease later in life.[41,42] While this chronic degenerative disease is not an immediate problem for most children, the habit of exercise and weight control inculcated in childhood can be helpful in decreasing risk of disease later in life. A fourth reason for encouraging vigorous physical activity is that it may decrease stress or emotionally related eating by furnishing something else to do in its place. The point here should be to stress a physical activity program and not simply exercise. Activity and exercise both are necessary to raise children's energy outputs.[43-46]

Oral Hygiene.—Frequent toothbrushing, swishing, and the use of dental floss and fluoridated water or supplements, regular dental care, as well as food choices low in retentive, fermentable carbohydrates also need to be stressed to ensure dental health.

Alcohol Use.—The use of alcohol is obviously to be discouraged in diets of individuals of these ages. However, surveys indicate that a sizeable proportion of adolescents drink alcoholic beverages and that more and more do so as they reach the third decade of life. Therefore, sensible advice about moderation in drinking is in order.

*Compared with 1979 recommended allowances, dietary goals, and present mean intakes of children and adolescents from the Health and Nutrition Examination Survey.
†RDA indicates recommended daily allowance—highest value for age-sex categories.

Examples of Menus

Table 7 provides a week's worth of menus that illustrate the types of dietary alterations that are called for if one wishes to feed children diets that approximate both the recommended allowances and the dietary goals. Table 8 shows the nutrients provided per day for the week's worth of menus and contrasts these to the relevant recommendations for children and adolescents. These menus meet the recommended allowances and also come quite close to the *Dietary Goals* for the United States (second edition) in most respects.[4] For children, and especially for adolescent girls, it is important to emphasize the use of skim milk to ensure that needs for calcium and vitamin D are met during periods of rapid growth. Girls, especially in late adolescence, may choose to use more liberal amounts of iron-fortified cereals for breakfast or whole grain and enriched cereal products to ensure that recommended allowances for iron and zinc are met. Young women also need to make a deliberate effort to keep their energy outputs up since this will permit them to eat more food (and more of these nutrients) while staying in energy

balance. For example, for those few girls of this age who are in energy balance at 2,400 calories, most of the recommended allowances would be met. However, at low levels of energy intake (eg, 1,800 calories), vitamins B_6, folic acid, and the minerals calcium, iron, and zinc would be in short supply.

Other points to emphasize are that salting of foods at the table should be discouraged, and that if sugary candies or confections are eaten, desserts included at meals should be eschewed. Children who consume less than 2,400 calories per day can be fed from these menus by decreasing the portion sizes provided; those who eat more can be fed by increasing the sizes.

Some children and adolescents prefer to eat light lunches, while others eat school lunches that provide ample (eg, one third of the recommended daily allowances) amounts of food. Either pattern can be compatible with good nutrition as long as it is kept in mind that the quality of snacks and foods eaten between meals is also important, and by the end of the day choices should approximate the food groups specified in the menus.

This study was supported by National Institutes of Health Career Development award K04-AM00272.

The menus presented in Table 7 are adapted from similar menus planned and calculated for adults by Frances Cronin, RD, PhD, Luise Light, EdD, Nancy Gaston, MS, Margaret Mitchell, MPH, and Susan Krebs, MPH, working under the direction of D. M. Hegsted, PhD, of the Human Nutrition Center, Science and Education Administration, US Department of Agriculture. Mary Mead, RD, MEd, and Carol Stollar, RD, MEd, of the Frances Stern Nutrition Center, offered assistance in revising menus to child tastes. Andrea Scarpa and Glenda Brown typed the manuscript. Candice Gibson, PhD, performed the calculations of the menus. The author accepts full responsibility for statements, calculations, and conclusions reached.

All rights reserved.

Indications: *ATTENUVAX® (Measles Virus Vaccine, Live, Attenuated, MSD)*—Active immunization against measles (rubeola) in children 15 months of age or older.
BIAVAX®II (Rubella and Mumps Virus Vaccine, Live, MSD)—Simultaneous immunization against rubella and mumps in children 15 months of age to puberty. May be given as early as 12 months if that offers greater convenience in scheduling.
MERUVAX®II (Rubella Virus Vaccine, Live, MSD)—Immunization against rubella (German measles) in children 15 months of age to puberty. May be given as early as 12 months if that offers greater convenience in scheduling. May be useful for adolescent and adult males to prevent or control rubella outbreaks in circumscribed population groups. In postpubertal females vaccination must not be undertaken unless the woman is not pregnant, is susceptible to rubella (as shown by Hemagglutination Inhibition test), agrees not to become pregnant for next three months (also in immediate postpartum period), and is informed of frequent occurrence of self-limited arthralgia and possible arthritis beginning two to four weeks after vaccination.
M-M-R®II (Measles, Mumps and Rubella Virus Vaccine, Live, MSD)—Simultaneous immunization against measles, mumps, and rubella in children 15 months of age to puberty.
M-R-VAX®II (Measles and Rubella Virus Vaccine, Live, MSD)—Simultaneous immunization against measles (rubeola) and rubella (German measles) in children 15 months of age to puberty.
MUMPSVAX® (Mumps Virus Vaccine, Live, MSD)—Immunization against mumps for children 15 months of age or older and adults. May be given as early as 12 months if that offers greater convenience in scheduling.

Contraindications: Pregnancy or the possibility of pregnancy within three months following vaccination (see special considerations for ATTENUVAX below); hypersensitivity to neomycin; any febrile respiratory illness or other active infection; for measles-containing vaccines, active untreated tuberculosis; therapy with ACTH, corticosteroids (except as replacement therapy, e.g., for Addison's disease), irradiation, alkylating agents, or antimetabolites; blood dyscrasias, leukemia, lymphomas of any type, or other malignant neoplasms affecting the bone marrow or lymphatic systems; primary immunodeficiency states, including cellular immune deficiencies, hypogammaglobulinemic and dysgammaglobulinemic states.

Hypersensitivity to Eggs, Chicken, or Chicken Feathers: For measles- and/or mumps-containing vaccines, in patients hypersensitive to eggs, chicken, or chicken feathers, weigh benefits of immunization against potential risks of hypersensitivity reactions.

Pregnancy: *ATTENUVAX*—The effects of ATTENUVAX on fetal development are unknown at this time. Live attenuated measles virus vaccine should not be given to persons known to be pregnant; furthermore, pregnancy should be avoided for three months following vaccination. Reports have indicated that natural measles during pregnancy enhances fetal risk. Increased rates of spontaneous abortion, stillbirth, congenital defects, and prematurity have been observed subsequent to natural measles during pregnancy. There are no adequate studies of the attenuated (vaccine) strain of measles virus in pregnancy. However, it would be prudent to assume that the vaccine strain of virus is also capable of inducing adverse fetal effects for up to three months following vaccination.
Vaccine administration to postpubertal females entails a potential for inadvertent immunization during pregnancy. Theoretical risks involved should be weighed against the risks that measles poses to the unimmunized adolescent or adult. Advisory committees reviewing this matter have recommended vaccination of postpubertal females who are presumed to be susceptible to measles and not known to be pregnant. If a measles exposure occurs during pregnancy, one should consider the possibility of providing temporary passive immunity through the administration of immune serum globulin (human).

Precautions: Administer subcutaneously; *do not give intravenously.* Epinephrine should be available for immediate use should an anaphylactoid reaction occur. Should not be given less than one month before or after immunization with other *live* virus vaccines, with the exception that ATTENUVAX, MUMPSVAX, and/or MERUVAX II may be administered simultaneously. BIAVAX II may be administered simultaneously with ATTENUVAX. Monovalent or trivalent poliovirus vaccine, live, oral, may be administered simultaneously with ATTENUVAX and/or MUMPSVAX. Vaccinations should be deferred for at least three months following blood or plasma transfusions or administration of more than 0.02 ml human immune serum globulin per pound of body weight. However, rubella vaccine may be given prior to discharge to susceptible postpartum patients who received blood products, provided that a repeat HI titer is drawn six to eight weeks after vaccination to insure seroconversion; similarly, although rubella vaccine may be given in the immediate postpartum period to those nonimmune women who have received anti-Rh_0 (D) immune globulin (human) without interfering with vaccine effectiveness, a follow-up postvaccination HI titer should also be determined.
Attenuated measles, mumps, and rubella virus vaccines, live, given separately, may result in a temporary depression of tuberculin skin sensitivity; therefore, if a tuberculin test is to be done, it should be administered before or simultaneously with any of these virus vaccines. Vaccination may not result in seroconversion in 100 percent of susceptible subjects.
Measles-Containing Vaccines—Due caution should be employed in children with a history of febrile convulsions, cerebral injury, or any other condition in which stress due to fever should be avoided. The physician should be alert to the temperature elevation which may occur 5 to 12 days after vaccination. The occurrence of thrombocytopenia and purpura has been extremely rare.
Rubella-Containing Vaccines—Excretion of live attenuated rubella virus from the nose and throat has occurred in the majority of susceptible individuals 7 to 28 days after vaccination. There is no confirmed evidence to indicate that such virus is transmitted to susceptible persons who are in contact with vaccinated individuals. Consequently, transmission, while accepted as a theoretical possibility, is not regarded as a significant risk.

Adverse Reactions: To date, clinical evaluation of the combination vaccines has revealed those adverse reactions expected to follow administration of the monovalent vaccines given separately.
Measles-Containing Vaccines—Occasionally, moderate fever (101–102.9 F); less commonly, high fever (above 103 F); rarely, febrile convulsions. Infrequently, rash, usually minimal without generalized distribution. Reactions at injection site. Local reactions characterized by marked swelling, redness, and vesiculation at the injection site of attenuated live measles virus vaccines have occurred in children who previously received killed measles vaccine; the combination vaccines were not given under this condition in clinical trials.
Experience from more than 80 million doses of all live measles vaccines given in the U.S. through 1975 indicates that significant central nervous system reactions such as encephalitis and encephalopathy, occurring within 30 days after vaccination, have been temporally associated with measles vaccine approximately once for every million doses. In no case has it been shown that reactions were actually caused by vaccine. The Center for Disease Control has pointed out that "a certain number of cases of encephalitis may be expected to occur in a large childhood population in a defined period of time even when no vaccines are administered." However, the data suggest the possibility that some of these cases may have been caused by measles vaccines. The risk of such serious neurological disorders following live measles virus vaccine administration remains far less than that for encephalitis and encephalopathy with natural measles (one per thousand reported cases). There have been reports of subacute sclerosing panencephalitis (SSPE) in children who did not have a history of natural measles but did receive measles vaccine. Some of these cases may have resulted from unrecognized measles in the first year of life or possibly from the measles vaccination. Based on estimated nationwide measles vaccine distribution, the association of SSPE cases to measles vaccination is about one case per million vaccine doses distributed, far less than the 5 to 10 cases of SSPE per million cases of natural measles.
Rubella-Containing Vaccines—Adverse reactions include malaise, sore throat, headache, fever, and rash; mild local reactions such as erythema, local pain, induration, tenderness, and regional lymphadenopathy; thrombocytopenia and purpura; allergic reactions such as urticaria; and arthritis, arthralgia that is infrequently associated with signs of inflammation, and polyneuritis.
Moderate fever (101–102.9 F) occurs occasionally, and high fever (103 F) occurs less commonly. Rash occurs infrequently and is usually minimal without generalized distribution. Encephalitis and other nervous system reactions have occurred very rarely.
Transient arthritis, arthralgia, and polyneuritis vary in frequency and severity with age and sex, being greatest in adult females and least in prepubertal children. In children, joint reactions are rare and of brief duration if they do occur. In women, incidence rates for arthritis and arthralgia are generally higher than those seen in children (children: 0–3 percent; women: 12–20 percent), and the reactions tend to be more marked and of longer duration. Rarely, symptoms may persist for a matter of months. In adolescent girls, the reactions appear to be intermediate in incidence between those seen in children and in adult women. Even in older women (35–45 years), these reactions are generally well tolerated and rarely interfere with normal activities.
Mumps-Containing Vaccines—Parotitis and orchitis. Rarely, purpura and allergic reactions such as urticaria. Very rarely, encephalitis and other nervous system reactions. With the monovalent mumps vaccine, mild fever occurs occasionally, and fever above 103 F is uncommon.

Shipment, Storage, and Reconstitution: During shipment, to insure that there is no loss of potency, the vaccine must be maintained at a temperature of 10 C (50 F) or less. Before reconstitution, store vaccines at 2–8 C (35.6–46.4 F) and *protect from light.* Use only diluent supplied to reconstitute vaccines. If not used immediately, store reconstituted vaccines in a dark place at 2–8 C (35.6–46.4 F), and discard if not used within eight hours. Use a separate sterile syringe and needle for each individual patient to prevent transmission of infectious agents from one person to another.
Color: The color of the vaccine when reconstituted is yellow. ATTENUVAX is acceptable for use only if clear.

How Supplied: *ATTENUVAX® (Measles Virus Vaccine, Live, Attenuated, MSD)*—Single-dose vials of lyophilized vaccine, containing when reconstituted not less than the equivalent of 1,000 $TCID_{50}$ (tissue culture infectious doses) of measles virus vaccine expressed in terms of the assigned titer of the FDA Reference Measles Virus, and approximately 25 mcg neomycin.
BIAVAX®II (Rubella and Mumps Virus Vaccine, Live, MSD)—Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than 1,000 $TCID_{50}$ of rubella virus vaccine, live, and 5,000 $TCID_{50}$ of mumps virus vaccine, live, expressed in terms of the assigned titer of the FDA Reference Rubella and Mumps Viruses, and approximately 25 mcg neomycin.
MERUVAX®II (Rubella Virus Vaccine, Live, MSD)—Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than the equivalent of 1,000 $TCID_{50}$ of rubella virus vaccine expressed in terms of the assigned titer of the FDA Reference Rubella Virus, and approximately 25 mcg neomycin.
M-M-R®II (Measles, Mumps and Rubella Virus Vaccine, Live, MSD)—Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than 1,000 $TCID_{50}$ of measles virus vaccine, live, attenuated, 5,000 $TCID_{50}$ of mumps virus vaccine, live, and 1,000 $TCID_{50}$ of rubella virus vaccine, live, expressed in terms of the assigned titer of the FDA Reference Measles, Mumps, and Rubella Viruses, and approximately 25 mcg neomycin.
M-R-VAX®II (Measles and Rubella Virus Vaccine, Live, MSD)—Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than 1,000 $TCID_{50}$ of measles virus vaccine, live, attenuated, and 1,000 $TCID_{50}$ of rubella virus vaccine, live, expressed in terms of the assigned titer of the FDA Reference Measles and Rubella Viruses, and approximately 25 mcg neomycin.
MUMPSVAX® (Mumps Virus Vaccine, Live, MSD)—Single-dose vials of lyophilized vaccine, containing when reconstituted not less than 5,000 $TCID_{50}$ of mumps virus vaccine expressed in terms of the assigned titer of the FDA Reference Mumps Virus, and approximately 25 mcg neomycin.
Each of these vaccines is supplied as a single-dose vial with a disposable syringe containing diluent and fitted with a 25-gauge, ⅝" needle, and as a box of 10 single-dose vials with an accompanying box of 10 diluent-containing disposable syringes with affixed needles.

Denouement and Discussion

Ota's Nevus

Fig 1.—Left, right, Typical macular pigmentation of sclera.

Fig 2.—Hyperpigmentation and discoloration of periorbital skin with almost complete blue "spilt-ink" discoloration of sclera.

Manifestations

Ota's nevus is a disorder of pigmentation characterized by macular lesions that may be tan, brown, slate gray, blue, purple, or black in color and that resemble a mongolian spot in appearance. Involvement is usually unilateral and affects areas innervated by the first, second, and occasionally the third division of the trigeminal nerve.

Approximately two thirds of the patients have scleral involvement ranging from small patchy lesions to an almost completely blue "spilt-ink" staining of the affected eye. Hyperpigmentation of the orbit and associated structures may also occur in the iris, cornea, ocular fundus, optic papilla, retrobulbular fat, periosteum of the orbital bone, or the optic nerve. Glaucoma of the involved eye has been reported.

Other areas of involvement include the mucous membranes of the nose and mouth, tympanic membrane, external auditory canal, neck, and rarely the leptomeninges.

It occurs more commonly in Oriental and black individuals and affects females more commonly than males. The nevus is present at birth in approximately 50% of the patients, and it is noted before age 21 in the majority of the cases. Although these lesions do not disappear, changes in color and shade can occur with age and during menses.

Histologically, dendritic, stellate, and fusiform melanocytes are diffusely scattered in the middle to upper dermis. Transformation into a malignant melanoma occurs in the brain, skin, and eyes and especially the iris. Malignant changes rarely take place in Orientals and blacks but occur in 5% to 15% of the white population with Ota's nevus. Reasons for this are unknown.

Genetics

No specific mode of inheritance has been documented.

Treatment

There is no specific treatment. Bleaching agents are apparently of no avail, but covering cosmetics may be useful. The occurrence, particularly in whites, of malignant transformation warrants periodic ophthalmologic examination.

Radiological Case of the Month

Lionel W. Young, MD; Contributed by Saskia v. W. Hilton, MD, David K. Edwards, MD

From the Department of Radiology, US Naval Regional Medical Center (Dr Hilton), and the Departments of Radiology and Pediatrics, University of California at San Diego (Dr Edwards), San Diego.

Reprint requests to Department of Radiology, Children's Hospital of Pittsburgh, 125 DeSoto St, Pittsburgh, PA 15213 (Dr L. W. Young).

A 6-week-old female infant was seen in the outpatient department for a fever of 24 hours' duration. Anteroposterior and lateral supine chest roentgenograms were performed (Fig 1) and the baby was admitted for evaluation of possible sepsis.

Previous medical history and the results of the physical examination were unremarkable. Cerebrospinal fluid via lumbar puncture was consistent with aseptic meningitis. Oblique chest roentgenograms (Fig 2) and a technetium Tc 99m medronate bone scan were obtained. The hospital course was uneventful and the patient was discharged after five days.

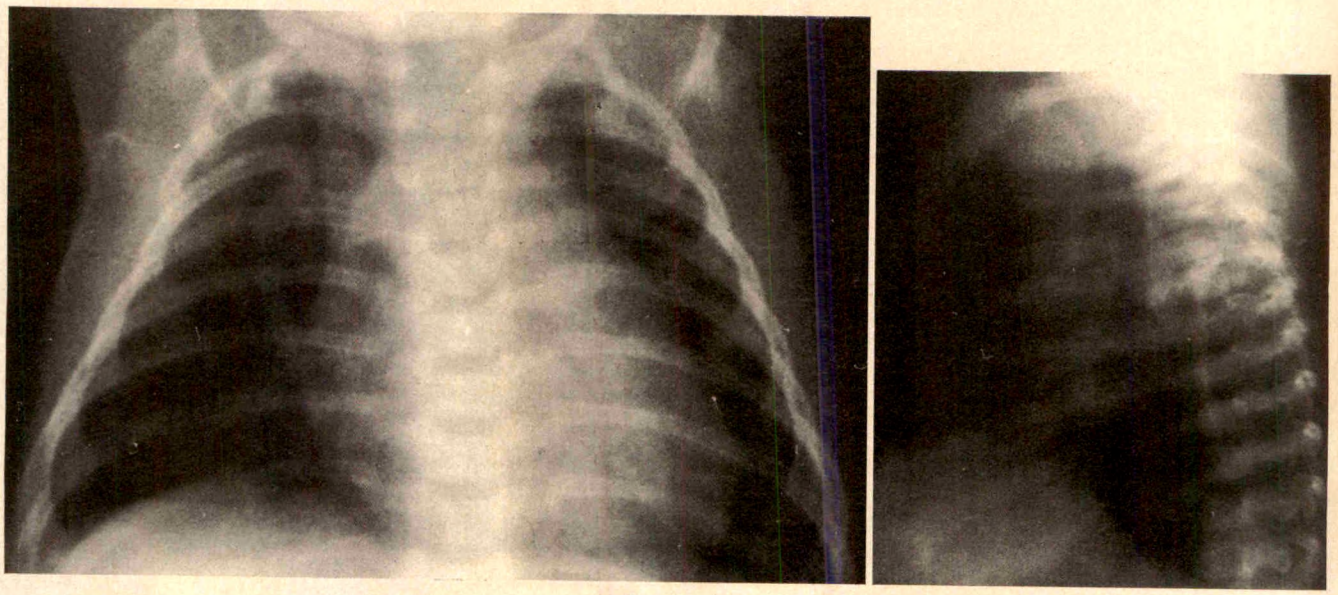

Figure 1.

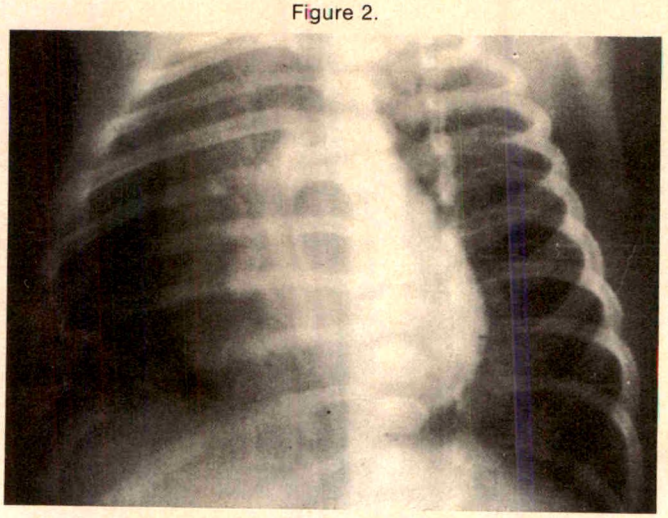
Figure 2.



Denouement and Discussion

Intrathoracic Rib

Fig 1.—Left and right, Chest roentgenograms show curved, radiodense structure adjacent to right cardiomediastinal silhouette in anteroposterior view, lying posteriorly in lateral view. Cephalad portion appears to blend with right fourth rib.

Fig 2.—Right posterior oblique view confirms that structure arises from anteromedial aspect of right fourth and fifth posterior ribs and has bony, rib-like appearance. Radionuclide bone scan (not shown) confirmed osseous nature of structure.

Though congenital anomalies of the ribs are common, intrathoracic ribs are extremely rare.[1] They are more frequently seen on the right than on the left and are usually single.[2] Generally, these originate posteriorly and extend downward and slightly laterally to end at or near the diaphragm[1]; in one case, an intrathoracic rib bridged the thorax internally.[3] The rib is always outside the parietal pleura, and the encasing pleural reflection can render the margins of the structure somewhat indistinct and thus hinder diagnosis.[4] However, the diagnosis is facilitated by knowledge of the condition; the structure "looks like a rib,"[5] and, unlike an anomalous vessel, it does not branch.[2] If the bony trabecular pattern cannot be discerned, a radionuclide bone scan is an easy and appropriate method of verifying its osseous nature.

It is important to recognize this structure as an innocuous anomaly so that needless manipulative examinations, and particularly surgery,[4] are not performed.

orange-pineapple flavored

Tuss-Ornade® cough/cold liquid

Each 5 ml. teaspoonful contains 5 mg. caramiphen edisylate; 2 mg. chlorpheniramine maleate; 15 mg. phenylpropanolamine hydrochloride; isopropamide iodide equivalent to 0.75 mg. of isopropamide; and alcohol, 7.5%.

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

INDICATIONS

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Lacking in substantial evidence of effectiveness as a fixed combination: For relief from coughing, upper respiratory congestion and hypersecretion associated with the common cold, sinusitis, vasomotor rhinitis and allergic rhinitis.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Hypersensitivity to any component; concurrent MAO inhibitor therapy; severe hypertension; bronchial asthma; coronary artery disease; stenosing peptic ulcer; pyloroduodenal or bladder neck obstruction. Do not use 'Tuss-Ornade' Liquid in children less than six months of age or under 15 lbs. in weight. Do not use 'Tuss-Ornade' *Spansule* capsules in children under 12 years of age.

Warnings: Warn vehicle or machine operators of possible drowsiness. Warn patients of possible additive effects of alcohol and other C.N.S. depressants.

Usage in Pregnancy: Use in pregnancy, nursing mothers and women who might bear children only when potential benefits have been weighed against possible hazards. An inhibitory effect on lactation may occur.

Effect on PBI Determination and I^{131} Uptake: The iodine in isopropamide iodide may alter PBI test results and will suppress I^{131} uptake; use thyroid tests unaffected by exogenous iodides.

Precautions: Use with caution in persons with cardiovascular disease, glaucoma, prostatic hypertrophy, hyperthyroidism. 'Tuss-Ornade' Liquid contains FD&C Yellow #5 (tartrazine), which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow #5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

Adverse Reactions: Drowsiness; excessive dryness of nose, throat or mouth; nervousness, insomnia; nausea, vomiting, diarrhea; rash; dizziness; weakness; tightness of chest; angina pain; abdominal pain; irritability; palpitation; headache; incoordination; tremor; difficulty in urination; thrombocytopenia, leukopenia; convulsions; hypertension, hypotension; anorexia; constipation; visual disturbances; iodine toxicity (acne, parotitis); dysuria; epigastric distress.

Supplied: 'Tuss-Ornade' Liquid: An orange-pineapple flavored liquid in 16 fl. oz. bottles. For patients 12 years or older, 'Tuss-Ornade' *Spansule* capsules (each capsule contains 20 mg. caramiphen edisylate; 8 mg. chlorpheniramine maleate; 50 mg. phenylpropanolamine HCl; and isopropamide iodide equivalent to 2.5 mg. of isopropamide), in bottles of 50 and 500 capsules.

That's what keeps CPT-4 the most current medical reporting system you can use!

The 4th Edition of *Physicians'* CURRENT PROCEDURAL TERMINOLOGY is the only coding system that provides new and revised terminology on a regular, automatic basis. This latest update, Summer 1980 marks the fourth update since CPT-4 was published in 1977.

The updates are on self-adhering pages that are affixed to the pages they replace in CPT-4. To activate the update mechanism, you simply return the postage-free card in the book.

CPT-4 is a uniform coding system to accurately designate medical, diagnostic, and surgical services in terms of a uniform language among physicians, patients, and third parties.

Shouldn't you be using the most current coding system available?

Order two—one for yourself, one for your medical records clerk.

For information about CPT-4 in computer tape format, write: Dept. of Applied Medical Systems, AMA, 535 N. Dearborn, Chicago, IL 60610.

Order Dept., OP-41
American Medical Association
P.O. Box 821
Monroe, Wisconsin 53566

Please send me_____ copy(ies) of *Physicians CURRENT PROCEDURAL TERMINOLOGY*, 4th Edition, OP-41. Price: $12 per copy. Enclosed is my check (payable to AMA) for $_____. Allow 4-5 weeks for delivery.

Ilosone® (erythromycin estolate)

WARNING

Hepatic dysfunction with or without jaundice has occurred, chiefly in adults, in association with erythromycin estolate administration. It may be accompanied by malaise, nausea, vomiting, abdominal colic, and fever. In some instances, severe abdominal pain may simulate an abdominal surgical emergency.

If the above findings occur, discontinue Ilosone promptly.

Ilosone is contraindicated for patients with a known history of sensitivity to this drug and for those with preexisting liver disease.

Indications: *Streptococcus pyogenes* (Group A Beta-Hemolytic) – Upper and lower respiratory tract, skin, and soft-tissue infections of mild to moderate severity.

Injectable penicillin G benzathine is considered by the American Heart Association to be the drug of choice in the treatment and prevention of streptococcal pharyngitis and in long-term prophylaxis of rheumatic fever.

When oral medication is preferred for treating the above-mentioned conditions, penicillin G or V or erythromycin is the alternate drug of choice.

The importance of the patient's strict adherence to the prescribed dosage regimen must be stressed when oral medication is given. A therapeutic dose should be administered for at least ten days.

Alpha-Hemolytic Streptococci (Viridans Group) – Short-term prophylaxis against bacterial endocarditis prior to dental or other operative procedures in patients with a history of rheumatic fever or congenital heart disease who are hypersensitive to penicillin. (Erythromycin is not suitable prior to genitourinary surgery when the organisms likely to lead to bacteremia are gram-negative bacilli or belong to the enterococcus group of streptococci.)

Staphylococcus aureus – Acute infections of skin and soft tissue which are mild to moderately severe. Resistance may develop during treatment.

S. (Diplococcus) pneumoniae – Infections of the upper respiratory tract (e.g., otitis media, pharyngitis) and lower respiratory tract (e.g., pneumonia) of mild to moderate severity.

Mycoplasma pneumoniae (Eaton Agent, PPLO) – Respiratory tract infections due to this organism.

Haemophilus influenzae – May be used concomitantly with adequate doses of sulfonamides for upper respiratory tract infections of mild to moderate severity. Not all strains of this organism are susceptible at the erythromycin concentrations ordinarily achieved.

Treponema pallidum – As an alternate treatment in penicillin-allergic patients. In primary syphilis, spinal-fluid examinations should be done before treatment and as part of follow-up after therapy.

Corynebacterium diphtheriae – As an adjunct to antitoxin, to prevent establishment of carriers, and to eradicate the organism in carriers.

C. minutissimum – In the treatment of erythrasma.

Entamoeba histolytica – For intestinal amebiasis only. Extraenteric amebiasis requires treatment with other agents.

Listeria monocytogenes – Infections due to this organism.

Legionnaires' Disease – Although no controlled clinical efficacy studies have been conducted, in vitro and limited preliminary clinical data suggest that erythromycin may be effective in treating Legionnaires' disease.

Contraindication: Known hypersensitivity to this antibiotic.

Warnings: (See Warning box above.) The administration of erythromycin estolate has been associated with the infrequent occurrence of cholestatic hepatitis. Laboratory findings have been characterized by abnormal hepatic function test values, peripheral eosinophilia, and leukocytosis. Symptoms may include malaise, nausea, vomiting, abdominal cramps, and fever. Jaundice may or may not be present. In some instances, severe abdominal pain may simulate the pain of biliary colic, pancreatitis, perforated ulcer, or an acute abdominal surgical problem. In other instances, clinical symptoms and results of liver function tests have resembled findings in extrahepatic obstructive jaundice.

Initial symptoms have developed in some cases after a few days of treatment but generally have followed one or two weeks of continuous therapy. Symptoms reappear promptly, usually within 48 hours after the drug is readministered to sensitive patients. The syndrome seems to result from a form of sensitization, occurs chiefly in adults, and has been reversible when medication is discontinued.

Usage in Pregnancy – Safety of this drug for use during pregnancy has not been established.

Precautions: Caution should be exercised in administering the antibiotic to patients with impaired hepatic function.

Recent studies of erythromycin reveal that its use in patients receiving high doses of theophylline may be associated with an increase in serum theophylline levels and potential theophylline toxicity. In such a case, the dose of theophylline should be reduced while the patient is receiving concomitant erythromycin therapy.

Surgical procedures should be performed when indicated.

Adverse Reactions: The most frequent side effects are gastrointestinal (e.g., abdominal cramping and discomfort) and are dose related. Nausea, vomiting, and diarrhea occur infrequently with usual oral doses.

During prolonged or repeated therapy, overgrowth of nonsusceptible bacteria or fungi is possible. If such infections arise, the drug should be discontinued and appropriate therapy instituted.

Mild allergic reactions, such as urticaria and other skin rashes, have occurred. Serious allergic reactions, including anaphylaxis, have been reported. [013079]

See adjoining column for summary of prescribing information.

Subacute Thyroiditis in a 4½-Year-Old Girl

Subacute thyroiditis is distinguished from "acute thyroiditis" by virtue of cause rather than mode of onset. Acute thyroiditis is bacterial in origin, usually with abscess formation. Subacute thyroiditis is generally thought to be viral. In 1973, Kirkland et al[1] reported a total of 36 cases of acute thyroiditis in children.[2] However, subacute thyroiditis is mentioned in only two pediatric case reports.[2,3] Studies in the adult literature mention five other cases of subacute thyroiditis.[4-8] We report an additional case in a 4½-year-old girl.

Report of a Case.—A 4½-year-old girl experienced fever and otitis media of the left ear six days prior to admission. Ampicillin sodium (250 mg) four times a day and a decongestant were given. The fever persisted, and she complained of dysphagia. Penicillin G benzathine (Bicillin), 600,000 units, was given. Two days later, anterior neck pain and thyroid swelling occurred.

Physical examination revealed a child in extreme discomfort, who kept her neck in a flexed position. Positive physical findings were limited to the head and neck region. Both tympanic membranes were retracted and dull. Her thyroid gland was exquisitely tender and diffusely enlarged to about three times normal size.

The WBC count was 15,700/cu mm, with 73% polymorphonuclear cells, 5% band forms, and 22% lymphocytes. The ESR was 58 mm/hr; urinalysis showed proteinuria (1+) and 3+ ketones, five to ten WBCs per high-power field (HPF), and ten to 20 RBCs per HPF on a centrifuged specimen. A repeated urinalysis 48 hours later showed normal findings.

The spinal fluid had no cells, a protein level of 11 mg/dL, and a glucose level of 83 mg/dL. A slide test for heterophil antibody of infectious mononucleosis was negative. The serum protein-bound iodine level was 11.3 mg/mL; serum thyroxine (T_4), (by radioimmunoassay) .12.1 mg/dL; triiodothyronine (T_3) uptake, 34%; serum thyroid-stimulating hormone (TSH), less than 1.5 μU/mL; and serum T_3, 118 ng/dL. Blood, urine, and throat cultures were negative. The serum amylase value was 5 IU/L (normal). Findings on ultrasound examination of the thyroid were consistent with diffuse enlargement secondary to edema. A test for antiepithelial thyroid antibodies was negative. Thyroid uptake (iodine 123) was 3.6% at six hours and less than 1.0% at 24 hours. This is consistent with thyroiditis. Normal values are 18% at six hours and 18% to 35% at 24 hours.

The patient continued to have daily spiking temperatures to 39.5 °C. Ampicillin therapy was continued, and after 48 hours, oxacillin (200 mg/kg daily) was added. There was no improvement after another 72 hours.

An endocrinology consultant believed that this child had subacute thyroiditis. Therefore, prednisone therapy (2 mg/kg/day) was started. She had one more temperature spike to 39.5 °C and then rapid defervescence. Her thyroid gland rapidly diminished in size and tenderness during the next 48 hours. She was discharged seven days after admission. Unfortunately, no viral cultures were taken.

Prednisone dosage was slowly decreased during an additional ten days. A T_3 uptake value was 27%; serum T_4, 6.9 mg/dL; and serum TSH, 8.2 μU/mL. Her gland returned to normal size and she has been asymptomatic for more than one year.

Comment.—As illustrated by this case, it is difficult to know whether one is dealing with an acute or subacute process when presented with a child with an acutely enlarged, tender thyroid gland.

Differential Diagnosis

	Acute (Suppurative) Thyroiditis	Subacute (Nonsuppurative) Thyroiditis
Age range	Rare in all age groups, but most common in children and young adults	Adults; extremely rare in children
Sex ratio	M = F	60%-100% F
Mode of onset	Acute	Often acute, but may be insidious
Fever	Present	Present
Thyroid swelling	Usually unilateral, often with fluctuant area	Usually diffuse, but may be unilateral or migrate between lobes
WBC count	Usually elevated with a left shift on differential cell count	Usually normal, but may be elevated to 20,000/cu mm; usually normal differential cell count
ESR	Elevated	Markedly elevated, often 100 mm/hr
Blood cultures	May be positive	Negative
Abscess	Present	Absent
Serum triiodothyronine and thyroxine levels	Normal	Usually normal; may see hyperthyroidism followed by a hypothyroid phase and a recovery period
Radioactive iodine uptake	No data	Decreased
Treatment	Antibiotics and drainage	Thyroid replacement and salicylates, steroids for severe cases

Differential diagnosis is important since the therapy is markedly different. Acute suppurative thyroiditis is often preceded by an upper respiratory tract infection or otitis media. Usual symptoms include fever, sore throat, dysphagia, and painful thyroid swelling. Usually, one lobe of the thyroid gland is enlarged, with warmth and erythema. This lobe later becomes fluctuant. There is usually leukocytosis with a left shift on the differential cell count and an elevated ESR. The patients are euthyroid. Ultrasonography can be helpful in identifying an abscess. The most common organisms are streptococci, staphylococci, and pneumococci,[9] although anaerobic bacteria have been reported recently.[10] Treatment consists of drainage of the abscess, cultures of the purulent material, and appropriate antibiotic therapy.

Subacute thyroiditis in adults was reviewed extensively by Greene in 1971.[11] Thyroid pain and swelling are the most consistent symptoms; the onset may be acute or insidious. Sore throat, fatigue, weakness, malaise, weight loss, and low-grade fever are often reported. Usually there is diffuse bilateral swelling. Swelling can also migrate from one lobe to another. The WBC count and differential cell count are usually normal. The ESR is always elevated, often higher than 100 mm/hr in the first month of illness. Normochromic anemia and decreased serum albumin and elevated globulin levels have been noted.[11] Thyroid function test results are usually normal, although the patient may become acutely hyperthyroid, presumably through release of preformed thyroid hormone from the damaged gland. This may be followed by a hypothyroid phase and then recover to normal function.[12,13]

Viral infections most often associated with subacute thyroiditis are mumps, measles, influenza, infectious mononucleosis, coxsackie virus, and adenovirus.[11] Treatment consists of thyroid replacement and salicylates for mild cases, with corticosteroid therapy reserved for the severely ill. The Table gives the pertinent distinguishing characteristics of these two diseases.

Liver Herniation Presenting as Respiratory Distress and Cardiomegaly

Respiratory distress and cardiomegaly in the immediate postnatal period are most frequently due to primary disease of the lungs or the vascular system. Herniation of the liver through the diaphragm into the chest cavity is rare, but can cause respiratory embarrassment and cyanosis.[1] Hypoplastic left heart syndrome, coarctation of the aorta, and Ebstein's anomaly of the tricuspid valve all may manifest cardiomegaly and respiratory distress.[2] Sepsis,[3] hypocalcemia,[4] and asphyxia[5] have also produced such findings. The following case report is one of congenital liver herniation manifesting respiratory distress and generalized cardiomegaly. Previously reported cases of liver herniation have not mentioned cardiomegaly as an early finding.

Report of a Case.—A 6-hour-old boy was admitted because of progressive tachypnea and cyanosis beginning one hour after birth. Vaginal delivery was uneventful, with Apgar scores of 8 and 9 at one and five minutes, respectively. Birth weight was 3,843.8 g. The 30-year-old mother is gravida 3, para 1, and in good health.

On physical examination, respirations were 90/min, heart rate 180 beats per minute, and rectal temperature was 37.3 °C. Blood pressure was 81/36 mm Hg in the right arm and 80/40 mm Hg in the right leg.

Laboratory tests revealed a normal hemoglobin level, WBC count, and differential count. An arterial blood sample while the baby was receiving 50% inspired oxygen showed a pH of 7.33, a P_{CO_2} of 32 mm Hg, and a P_{O_2} of 117 mm Hg. Serum electrolyte, calcium, and glucose levels were normal.

The chest roentgenogram was interpreted as showing massive cardiomegaly (Fig 1 and 2) and possible elevation of the right hemidiaphragm. An echocardiogram excluded pericardial effusion and was negative for intramyocardial masses. The ECG was normal for age.

Right-sided heart catheterization demonstrated elevated right ventricular and pulmonary artery pressures (50/0-6 mm Hg and 50/30 mm Hg, respectively). Angiography showed that the heart and left lung were displaced into the left thoracic cavity by a nonvascular mass. The venous return, arterial system and size, and configuration of the heart's chambers were normal.

The chest was opened with a midline sternotomy to reveal a distended pericardial sac containing 15 mL of fluid. At opening of the pericardium, a 4 × 6-cm saccular mass was found. The mass displaced the heart and indented the lateral wall of the right ventricle. The sac then was opened and revealed liver tissue. After returning the liver to the abdomen, the eventrated portion of the diaphragm was

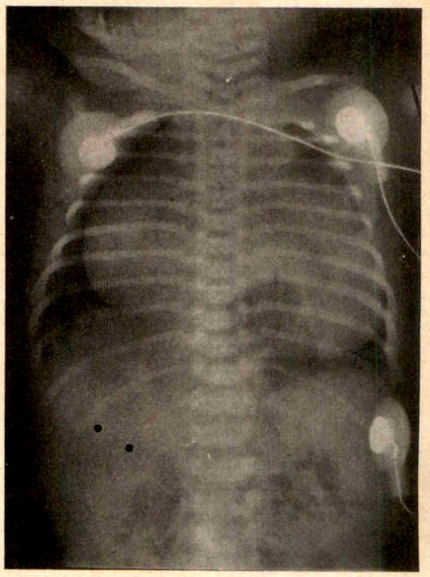

Fig 1.—Chest roentgenogram showing generalized cardiomegaly.

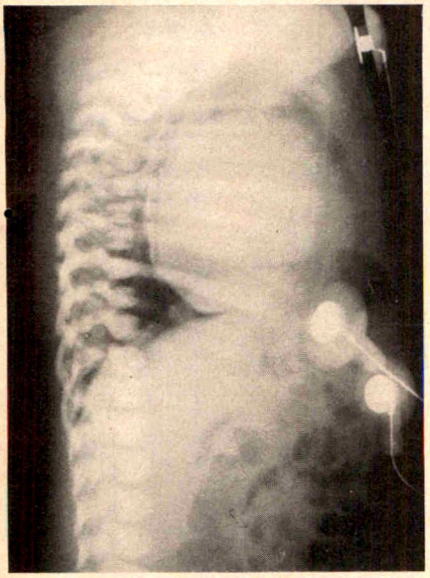

Fig 2.—Chest roentgenogram, lateral view, showing generalized cardiomegaly.

repaired with direct sutures that extended to the chest wall anteriorly. The postoperative course was uneventful. A postoperative roentgenogram revealed a normal cardiac silhouette.

Comment.—Developmentally and anatomically, the diaphragm is an organ with several potential points for herniation, the most frequent sites being the foramen of Bochdalek, the esophageal hiatus, and the foramen of Morgagni.[6] Diaphragmatic herniation on the left is 12 times as common as on the right, with the bowel being the most common organ found in the chest cavity.[7] Liver herniation is extremely rare. A review of 83 hernias through the foramen of Morgagni revealed one case of combined liver and colon herniation; no cases had only liver in the sac.[8]

Respiratory difficulties and increase in the size of the heart in the immediate postnatal period are most commonly ascribed to congenital heart disease such as hypoplastic left heart syndrome, Ebstein's anomaly of the tricuspid valve, coarctation of the aorta, and truncus arteriosus. Infants of diabetic mothers and severely hypoglycemic neonates may have combined cardiorespiratory symptoms. Sepsis and hypoglycemia have also been reported to cause such findings.

This case demonstrates that although herniation of the liver through the right diaphragm is infrequent, it should be considered in the infant with respiratory distress and cardiomegaly. Aids to diagnosis prior to surgery may include chest roentgenography,[9] liver scan,[10] pneumoperitoneum,[11,12] echocardiogram, and cardiac catheterization. Therapy prior to surgery should be directed toward the relief of symptoms; the asymptomatic infant may require no invasive procedures.

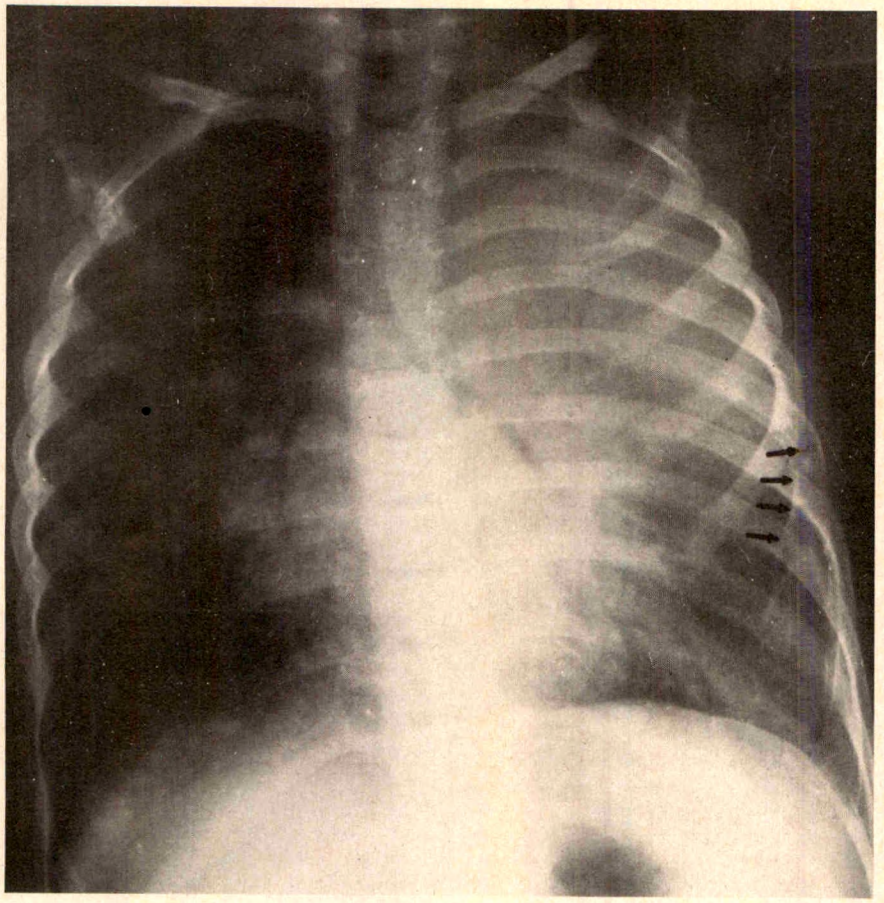
Aspergillosis in Chronic Granulomatous Disease: Therapeutic Considerations

Children with chronic granulomatous disease (CGD) are susceptible to a wide variety of catalase-positive microorganisms.[1] *Aspergillus* infections are particularly difficult to diagnose and treat. Aspergilli may invade many tissues, including the lung,[1,2] thyroid,[3] and bone,[4] and diagnosis frequently requires culture of surgical specimens. Therapy for aspergillosis in children with CGD by use of amphotericin B alone is frequently suboptimal, and several patients have required granulocyte transfusions in addition to amphotericin B.[1,2] The need for potentially synergistic combinations of antimicrobials is particularly keen in children with CGD. We report a case of aspergillosis involving the ribs, lung, and pleura that was successfully treated with the combination of amphotericin B and rifampin.

Method of Susceptibility Testing.—The clinical isolate of *A fumigatus* was grown on Sabouraud's ager slants for seven days. The method of harvesting and quantitating the inocula of the aspergillus and the control organism *Candida albicans* as well as the preparation of amphotericin B and flucytosine is described elsewhere.[5] Rifampin was similarly prepared except that it was initially dissolved in methyl alcohol. Susceptibility testing was performed using a tube dilution method described by Shadomy and Espinel-Imgrao.[6] Synergy was tested for using standard checkerboard techniques. In both drugs, a fourfold decrease in the concentrations necessary to produce inhibitory or lethal activity was considered synergistic. Any decrease in concentrations less than fourfold was considered additive.

Report of a Case.—A 27-month-old male infant known to have CGD was readmitted to State University of New York Hospital, Brooklyn, with a history of fever and a fluctuant mass over the left lateral chest wall. X-linked CGD was diagnosed at 6 months of age when a *Serratia marcescens* osteomyelitis of his calcaneus developed. He was successfully treated, and therapy was begun with sulfamethoxazole and trimethoprim for the 18 months prior to his readmission. The diagnosis of CGD was based on a negative qualitative nitroblue tetrazolium test (NBT) with and without endotoxin stimulation, a markedly reduced quantitative NBT test, and an abnormal microbial killing assay. On physical examination, he appeared to be acutely ill with a temperature of 38.3 °C. Two tender masses were noted over the lateral aspect of his left hemithorax. Chest films revealed extensive left-sided pulmonary infiltration and pleural reaction (Figure). Lytic lesions and periosteal reaction were also noted in the left fourth, fifth, sixth, and seventh ribs. A gallium citrate Ga 67 scan confirmed the presence of inflammation in these ribs. Serology performed to a variety of fungi revealed a complement fixation (CF) titer of 1:64 for *Aspergillus*. One of the masses overlying the chest was explored, and pus containing septate



Lytic lesions and periosteal reaction noted in left fourth, fifth, sixth, and seventh ribs (arrows).

hyphae on stain with lactophenol cotton blue was obtained. *Aspergillus fumigatus* grew in pure culture from the purulent material obtained from these masses as well as from a biopsy specimen of the rib and bone marrow aspirate. Susceptibility testing of the *Aspergillus* to flucytosine, amphotericin B, and rifampin, as well as synergy studies, were performed (Table). The child was begun on therapy with amphotericin B, 0.2 mg/kg/day, and the dosage was gradually increased to 1 mg/kg/day. He was also given rifampin, 10 mg/kg/day orally in two doses. He received alternate-day therapy with amphotericin B after a serum level of 1.95 μg/mL had been achieved. Gradual healing of the lytic areas in his ribs occurred, and he was maintained on a regimen of alternate-day amphotericin B for two months. He was discharged from the hospital on a rifampin regimen and was given amphotericin B twice weekly as an outpatient. His total dose of amphotericin B was 380 mg at the time of its discontinuation four months after admission. Repeated serology studies performed six weeks after therapy was begun showed a CF reaction to *Aspergillus* of 1:16 and a titer of 1:4 four months after admission. The child appears well, without recurrence of his aspergillosis nine months since his discharge from the hospital.

Comment.—Children with chronic granulomatous disease have an immunologic defect inherent in their phagocytes. In most families, this defect is inherited through an x-linked gene.[7] Although neutrophils from these children migrate and phagocytize bacteria and fungi, they are unable to kill those that are catalase positive, thereby leading to the intracellular persistence of these organisms. Once an infection has occurred, specific therapy should be instituted, where feasible, with bactericidal activity that penetrates phagocytes well. When these therapeutic criteria cannot be met or therapy appears unsuccessful, granulocyte transfusions may be necessary.[1,2,8] Our patient had osteomyelitis with an *Aspergillus* whose minimum inhibitory concentration (MIC) was within easily achievable serum levels of amphotericin B and whose minimum lethal concentration was at maximally achievable serum concentrations (Table). The combination of amphotericin B and rifampin has been shown to be synergistic for some aspergilli in vitro[9] and in animal models.[10] Kitahara et al[9] found this combination to be synergistic in vitro against six of six clinical isolates of aspergilli as evidenced by a marked decrease in MICs, the incorporation of tritium uridine into RNA, and growth weights of the aspergilli when compared with those obtained by amphotericin B alone. Similarly, Arroyo et al[10] found the addition of rifampin to amphotericin B superior to amphotericin B alone in the therapy of disseminated aspergillosis in mice as judged by a significantly higher survival rate in those mice receiving combined therapy. Depending on the inoculum size and dose of rifampin added to amphotericin B, 40% to 100% of mice survived on combined therapy, 10% to 30% on amphotericin B alone, and 0% to 10% of controls after one month of observation. These studies suggest that combination chemotherapy may prove to be of benefit in aspergillosis as it has in other fungal infections.[11] As can be seen in the Table, rifampin also synergistically potentiated the lethal activity of amphotericin B for our isolate in vitro and we believed that it might decrease either the dose or duration of amphotericin B therapy required for successful treatment. The "static" and lethal activity of amphotericin B was also increased in vitro by flucytosine. The degree of potentiation was not as marked, however, as that observed with rifampin. It should be noted that when the concentration

Antimicrobial Therapy Against *Aspergillus fumigatus**

	MIC	MLC
Rifampin	>64	>64
Flucytosine	>250	>250
Amphotericin B	0.98	1.95
Rifampin/amphotericin B	0.08/0.5	1.25/0.5
Flucytosine/amphotericin B	0.12/0.5	62.5/0.5

*Minimum inhibitory concentration (MIC) and minimum lethal concentration (MLC), measured in micrograms per milliliter, of rifampin, flucytosine, and amphotericin B alone and in combination.

of amphotericin B was decreased to 0.25 μg/mL, neither lethal nor inhibitory activity could be demonstrated against our isolate no matter what concentrations of flucytosine or rifampin were added. The resolution of the lytic rib lesions and the patient's thoracic granulomata and the decrease in his CF titers suggest that the combined use of rifampin and amphotericin B should be considered in a child with CGD and aspergillosis.

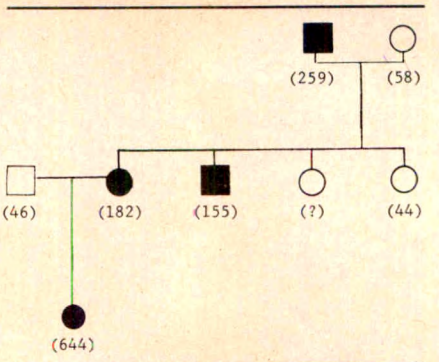
Asymptomatic Familial Elevation of Serum Alkaline Phosphatase Levels

Asymptomatic elevation of serum alkaline phosphatase levels has been reported recently in one family. An autosomal dominant inheritance was suggested by father-son transmission.[1] Both liver and bone isoenzyme levels were elevated. We describe another family that had elevations of serum alkaline phosphatase levels without apparent disease. In this family, the heat labile fraction (representing the bone isoenzyme level) was greater than 90% in all affected individuals.

Report of a Case.—An 11-year-old asymptomatic girl was found to have an elevated serum alkaline phoshatase level after the incidental discovery of an increased level in her mother. Extensive investigations failed to reveal a cause for the elevated level in the mother. Results of a physical examination of the daughter were entirely normal. Results of laboratory studies, including complete blood cell count, urinalysis, and serum chemistries, were normal except for a fasting serum alkaline phosphatase level of 664 IU/L (normal, 40 to 110 IU/L). Other laboratory values were as follows: SGPT, 11 IU/L (normal, ≤ 40 IU/L); serum γ-glutamyl transpeptidase, 13 IU/L (normal, 2 to 40 IU/L); serum 5′nucleotidase, 8 Bodansky units/mL (normal, 2 to 17 BU/mL); albumin-globulin ratio, 1.7; serum ceruloplasmin, 38 mg/dL (normal, 20 to 50 mg/dL); serum α_1-antitrypsin, 170 mg/dL (normal, 150 to 275 mg/dL); serum calcium, 9.2 mg/dL; and serum phosphorus, 3.8 mg/dL. Subsequent evaluations revealed persistently elevated serum alkaline phosphatase levels, negative hepatitis B surface antigen, and negative urinary viral isolation studies. Roentgenographic examinations revealed a normal oral cholecystogram and skeletal survey. An isotopic bone scan was normal. Serum alkaline phosphatase activity determined by the International Method was 96% heat labile. Evaluation of the mother's enzyme activity revealed 92% to be heat labile. The enzyme activity of a maternal uncle and grandfather was also predominantly heat labile (94%) (Fig 1). A dietary history showed no deficiency.



Family pedigree, with top being maternal grandparents, middle, parents and maternal uncle and aunts, and bottom, patient of our study. Solid symbols indicate members with elevated serum alkaline phosphatase activity; open symbols, members with normal activity; squares, males; circles, females. Numbers in parentheses represent serum alkaline phosphatase values, IU/L (normal, 40 to 110 IU/L).

Comment.—An elevated serum alkaline phosphatase level unrelated to physiological conditions such as skeletal growth or pregnancy is often regarded as evidence of a pathologic condition.[2] Pathologic elevations of serum alkaline phosphatase levels are most often associated with disorders of the liver and bone; however, a wide variety of diverse diseases may occasionally cause an elevation in the enzyme level. Disorders causing an elevation of the heat labile fraction of the enzyme are as follows: physiologic growth, fractures, primary and secondary hyperparathyroidism, osteomalacia, rickets, Paget's disease, primary or metastatic neoplasms, acromegaly, polyostotic fibrous dysplasia, osteogenesis imperfecta, familial osteoectasia, hereditary osteolysis, and primary hypophosphatemia.[2-5,7]

As there are usually many other signs, symptoms, or laboratory abnormalities indicating disorders of liver or bone, there is often no need to identify the specific isoenzymes.[3] However, when an elevation of the serum alkaline phosphatase level is found in an otherwise healthy person, an identification of the source of the enzyme is desirable.[3] This determination may be accomplished directly by heat or urea stability tests, electrophoretic separation, or amino acid inhibition testing, or indirectly by determination of other hepatobiliary enzymes such as 5′nucleotidase, leucine aminopeptidase, and γ-glutamyl transpeptidase.[5,6]

An asymptomatic family was recently described in which elevations in

serum alkaline phosphatase levels seemed to be inherited in an autosomal dominant manner.[1] There was increased activity of both bone and liver isoenzymes. In the family we examined, elevations of the enzyme levels in the absence of disease seemed to be transmitted in an autosomal dominant manner as well. However, the presence of a predominantly heat labile fraction would suggest a different abnormality in enzyme homeostasis in the two families. The evaluation of elevated serum alkaline phosphatase levels should include enzyme determinations in family members if other diagnostic studies are inconclusive.

Argininosuccinicaciduria: The Hair Abnormality Revisited

Argininosuccinicaciduria is a rare genetic error of the Krebs-Henseleit urea cycle due to the absence or deficiency of the enzyme argininosuccinate lyase and is associated with mental retardation, seizures, ataxia, and hepatomegaly. Hyperammonemia may or may not be present, but blood urea levels are always within normal limits. Abnormally fragile hair has been detected in about half of the reported cases, and in some, a morphologic hair alteration termed trichorrhexis nodosa has been observed.[1] The nature of the hair defect has not been extensively studied, and tensile strength and other physical properties have been measured in only a single case, to our knowledge.[2] Amino acid analysis of acid hydrolysates of our patient's hair revealed a reduction in cystine content to 50% of the control level, concomitant with a similar degree of reduction of values for tensile strength and Young's modulus. No relationship between the urea cycle block, the amino acid alteration in hair protein, and the phenotypic expression of the disorder, particularly the mental retardation, could be established or discerned.

We have continued to study this patient for seven years. The urinary excretion of argininosuccinic acid continues unabated at the same order of magnitude as during the period of the initial diagnoses (2.5 mM/g creatinine), and the child remains severely mentally retarded. However, a distinct improvement in hair appearance has occurred together with a substantial increase in hair cystine content to about 75% of the normal level. Measurement of tensile strength and Young's modulus at this time similarly revealed a notable change in the direction of normal values.

Comment.—Amino acid analysis and measurement and calculation of physical attributes were carried out as previously described.[2] Assessment of intellectual function was made by neurological examination and by reports of special education instructors.

Figure 1 summarizes the results of cystine measurements, tensile strength, and Young's modulus values as a function of age and as a percentage of the normal value. Control measurements were made using hair obtained from six age-matched, nonhospitalized neighborhood children apparently in good health. A gradual increase in cystine content and tensile strength occurred between 5 and 10 years of age, with a marked additional improvement over the next two years. The figure also shows that a much earlier and more pronounced increase in values for Young's modulus occurred. Thus, correction of the defect in the elastic properties of the hair preceded and exceeded the correction in overall tensile strength and total cystine content.

Figure 2 compares the appearance of the hair at diagnosis and seven years later. The mother reports that the child's pillow is not now covered with short, broken-off fragments of hair as it had been during the initial period of study. Early speculations concerning the abnormality were related to a possible arginine deficiency in the hair.[1] An improvement in quality and/or quantity of the hair was reported to have occurred after supplementation of the diet with arginine[3] or with a high protein content.[4] However, arginine levels were not measured either before or after treatment in these cases. In our patient, arginine levels in the hair were dis-

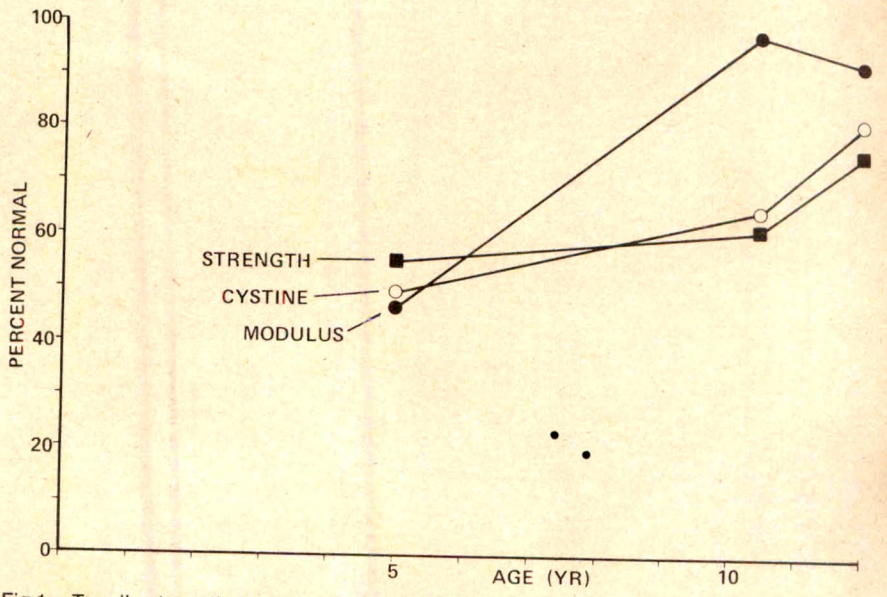

Fig 1.—Tensile strength, Young's modulus, and cystine content as function of age in hair of patient.

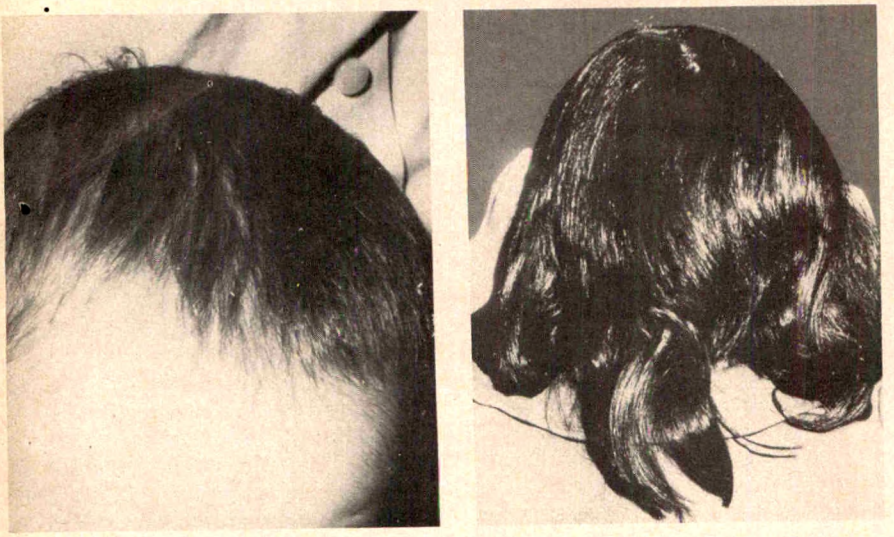

Fig 2.—Appearance of patient's hair at diagnosis (left) and seven years later (right).

tinctly within the normal range. Baden and Shih[5] have described two patients with normal amino acid levels in the hair, but it was not stated whether the hair was brittle in these patients. It is of interest that the sulfur-containing amino acids play a major role in the altered chemical and physical properties of hair in both acquired and genetic disorders.[6,7] The water content of the patient's hair, determined by the method of Gold and Scriver,[6] was not notably different from the normal control hair.

R. J. Pollitt has reported (written communication, July 17, 1974) that the brittle hair of one of the first patients discovered with this disorder now appears to be completely normal 20 years later, but no chemical or physical measurements were mentioned. Not enough information is available at this time to even speculate whether the hair defect is genetic and related to the urea cycle block, genetic and unrelated, acquired, or some combination of these factors. Similarly, the cystine deficiency cannot reasonably be related to the primary enzymic deletion. However, a clinical appraisal of the quality, quantity, and distribution of body hair should remain an important facet of the physical examination of any patient. The initial indication for an amino acid workup in our patient was based on the observation by an astute house officer who commented on the shortness of the patient's hair, though it had not been recently cut. The structure of keratin in normal and abnormal states represents a complex problem in the chemistry and physical chemistry of an abundant and easily obtainable protein. Its alteration in genetic and acquired diseases and susceptibility to hormonal influences are important facets of biologic mechanisms, and its study may reveal clues related to the basic mechanisms of underlying diseases.[8]

CORRECTION

Phrase Omitted.—In the article entitled "Hypernatremic Dehydration of Infancy," published in the August JOURNAL (134:785-792, 1980), a phrase was inadvertently omitted. On page 789, in the second column, second paragraph, the third sentence should have read as follows: "Two studies in Great Britain have shown that a random urine osmolality is likely to be higher in a healthy formula-fed infant than in a healthy breast-fed infant."

Letters to the Editor

Correspondence pertaining to material published in the JOURNAL will be published, if found suitable, as space permits. Submit double-spaced copy clearly marked "For publication" and signed by all authors; references should conform to JOURNAL format; maximum length: 500 words. Copyright assignment signed by all authors is required. The Editor reserves the right to edit such letters, which should be received within six weeks of publication of the JOURNAL article in question.

Bartter's Syndrome

Sir.—I read with interest in the JOURNAL (133:636-638, 1979) the article by Robson, Arbus, and Balfe, "Bartter's Syndrome: Differentiation Into Two Clinical Groups"; it confirms the findings I published with David et al in 1976.[1] In addition, I observed that the infusion of angiotensin II produced an increase in urinary sodium excretion only in the patients with sodium wasting and that this renal sodium wastage occurred despite an increased aldosterone secretion.

I could not confirm some points made by the authors about the difference between the two groups. There was no difference in age between the two groups; the two patients with salt wastage were seen after the age of 3 years (5½ and 13 years), and the youngest of our patients (3½ years) showed no sodium wastage. Our findings were similar to those of Wald et al.[2] Hypomagnesemia was observed only in our patient with sodium wastage.

The reason or reasons why some patients exhibit sodium wastage and others do not is not, to my knowledge, known. According to our preliminary results, infusion of saralasin acetate (an inhibitor of angiotensin II that lowers the secretion of aldosterone) produced an increase in urinary sodium excretion in a patient without sodium wastage, whereas no change of urinary sodium excretion was observed in a patient with sodium wastage. These results suggest that the patients with sodium wastage would exhibit an escape from aldosterone activity that is not observed in the patients without renal sodium wastage. The existence or absence of sodium wastage in Bartter's syndrome raises also the problem of whether the etiology is similar in the two groups.[2,3]

3. Godard C, Valloton MB, Broyer M, et al: A study of the inhibition of the renin angiotensin system in potassium wastage syndrome, including Bartter's syndrome. *Helv Paediatr Acta* 27:495-512, 1972.

In Reply.—Bartter's syndrome is indeed an intriguing disease to study and we welcome comments such as those of Dr Sann. We found some of his comments confusing. The only similarity between our two articles was that both suggest that some patients with Bartter's syndrome are sodium losers whereas others are not, a fact we documented with ten references in our article. Otherwise, we attempted to separate these two groups (salt losers and non-salt losers) based on biochemical (plasma sodium, potassium, chloride, magnesium, calcium, and bicarbonate levels, renin activity, and blood pH) and historical (age, tetany, and episodes of volume depletion) differences, whereas the article by Sann et al separates the two on the basis of an angiotensin II infusion. Also, we have not found any reference to hypomagnesemia in the communication by Sann et al and assume that their comment on this subject has not yet been published.

We believed that the age difference between our two groups pointed up the possibility that salt losers might eventually become non-salt losers. The findings of both types of Bartter's syndrome in the one family we studied suggested that the etiology of the conditions of the two groups might in fact be similar, the major difference being in kidney maturation or compensation. Thus, sodium losers should be monitored periodically to ensure that any onset of normal renal sodium conservation is detected, "at which time treatment would be altered." However, it must be remembered that this is a syndrome, and therefore there is a possibility of having several etiologies.

Molybdenum Metabolism

Sir.—We have read with interest the review articles on trace elements in the young infant by Dr Shaw (JOURNAL 133:1260-1268, 1979; 134:74-81, 1980). It is evident that knowledge of trace-element metabolism is of growing importance in the study of many diseases. Although Dr Shaw gives an excellent treatment of some of the well-known trace elements, we would like to comment on his decision to omit a discussion of molybdenum "because so little is known about its role in the metabolism of the fetus and young infant."

A considerable amount of knowledge about molybdenum metabolism in humans has been gained over the past few years. For example, an inverse relationship between copper and molybdenum levels in fetal liver has been established.[1] In addition, it is now known that molybdenum is an essential component of the human.

enzymes sulfite oxidase, xanthine dehydrogenase, and aldehyde oxidase.[2] The metal in these enzymes is present in the form of a molybdenum cofactor. The complete structure of this cofactor is not, to our knowledge, known yet, but the presence of a novel pterin moiety in the molecule has been demonstrated.[3]

Recently, a patient's condition has been diagnosed as a combined deficiency of sulfite oxidase and xanthine dehydrogenase.[4,5] The combined deficiency in this individual has been shown to result from an absence of active molybdenum cofactor.[6] The patient has all the clinical symptoms that have been associated with sulfite oxidase deficiency: severe mental retardation, seizures, and bilateral lens dislocation, in addition to many minor dysmorphic features. These symptoms were present almost from birth. Xanthinuria was evident from the presence of small xanthine stones in the urine. Direct clues to the diagnosis were the finding of low plasma uric acid concentrations (0.01 to 0.06 mmole/L) and a positive sulfite test of the urine (Merckoquant Sulfit Test, Merck, Darmstadt, West Germany). Therapeutic trails with oral supplements of ammonium molybdate and inorganic sulfate failed to produce clinical or biochemical improvement.

The patient described above is, to our knowledge, the first person identified with an inborn error in molybdenum metabolism expressed as a combined deficiency of two molybdoenzymes. It is hoped that future studies of this patient will lead to a better understanding of the metabolism and biological function of molybdenum. This information should in turn be of value in better judging the daily requirements for this trace element under normal circumstances and in special situations such as in patients receiving parenteral nutrition.

Circumcision

Sir.—In his article in the JOURNAL (134:301-302, 1980), Woodside describes one of the many complications of male circumcision. I applaud his effort to bring it to our attention but I disagree with his conclusion. After detailing the course of fasciitis and sepsis depicting scarified abdomen and genitalia in an infant circumcised on the sixth day of life, he criticizes the technique used and advises a "safer" one.

The Committee on Fetus and the Newborn of the American Academy of Pediatrics, quoted by Woodside, declares that there is no medical indication for routine circumcision in the neonatal period. I submit, therefore, that performance of this procedure—an acknowledged hazard to health—constitutes child abuse. Physicians should prevent, not abet, unhealthful practices.

MICHAEL KATZ, MD
Department of Pediatrics
College of Physicians
and Surgeons
Columbia University
New York, NY 10032

In Reply.—I concur that no valid medical indication exists for routine neonatal circumcision and I do not advocate its practice. In reality, however, some parents will continue to request and obtain circumcision for their male infants. Those neonates then deserve to receive a meticulously performed operation, using the safest available technique. In my opinion, Gomco circumcision is the preferred technique.

Thiamine-Deficiency-Related Cardiac Failure

Sir.—I found the article by Moran and Greene in the February 1979 issue (133:192-199) generally edifying, but wanted to write concerning their recommended management of thiamine-deficiency-related cardiac failure on page 195. They state, "treatment of thiamine deficiency . . . in severe cases 10 mg intravenously . . . resolves . . . cardiac symptoms in 24 to 48 hour. . . . In critically ill adults, 100 mg/day of thiamine parenterally may be necessary."

I believe it would be better to emphasize an approach of initially controlling the cardiac failure by administering digitalis and diuretics. This is because administering thiamine 100 mg intravenously initially might throw the patient into worsening forward failure by increasing metabolic efficiency before the cardiovascular improvement has asserted itself.

I recall a patient seen many years ago in whom a diagnosis of beriberi heart disease was made and who was

given 100 mg thiamine intravenously the night of admission. He died next morning, though he had been in no notable distress on admission. To my recollection, he had had edema for some weeks.

I have not found much on this question in the US literature and would be interested in comments from Greene and Moran. Perhaps a review of the foreign literature would be rewarding.

MICHAEL ANTESKI, MD
479 N Cary St
Brockton, MA 02402

In Reply.—When the diagnosis of beriberi heart disease is considered in an individual patient, it should be kept in mind that the genesis of the cardiovascular abnormalities are diverse and a number of variations in initial observation have been recognized.[1] First, there are the classic "wet" forms, in which signs and symptoms of right-sided heart failure with normal or high cardiac output are the initially observed symptoms. Second, a fulminant or "pernicious" variant, termed Shoshin (from the Japanese *sho*, meaning acute damage, and *shin*, meaning heart), may occur with severe biventricular failure, metabolic acidosis, variable cardiac output with vascular collapse, peripheral cyanosis, and death. Treatment of beriberi therefore must be along two main lines: correcting the underlying defect, and treating the clinical manifestations. Obviously, thiamine replacement is the cornerstone of therapy. Treatment of the acidosis with sodium bicarbonate is necessary in critical cases, but it may have only limited success until thiamine replacement is given. Heart failure must be treated with oxygen, diuretics, rest, and salt restriction. Treatment with digitalis, though debatable, is probably justified in acute cases to prevent rapid development of low-output failure and sudden death, as seen in some cases.[2]

In addition to beriberi, other known forms of heart disease may be present in these patients. Recognition of such combinations has obvious therapeutic implications.

Finally, the direct toxic effect of alcohol on the myocardium and the syndrome of alcoholic cardiomyopathy are well known. This is probably one of the causes of persistent cardiomegaly following treatment of beriberi with thiamine.

Books

Hemoglobinopathies in Children, edited by Elias Schwartz, 402 pp, with illus, $27.50, Littleton, Mass, PSG Publishing Co Inc, 1980.

The application of recently developed technology to the study of hemoglobin synthesis has led to a sudden expansion of the literature that deals with the hemoglobinopathies and thalassemia. Complete chromosome mapping of the globin genetic regions has been accomplished with bacterial restriction endonucleases, and sequence analysis of DNA and RNA has been facilitated with "probes" of complementary DNA and recombinant technology. As a result, the genetic and molecular flaws underlying disorders of hemoglobin synthesis can be defined with far greater precision than has heretofore been possible. *Hemoglobinopathies in Children,* the third volume in the *Progress in Pediatric Hematology and Oncology* series, is welcomed as a timely synthesis of this newly acquired knowledge. It is authored by 27 persons active in the field and edited by Elias Schwartz, whose clinical and laboratory contributions to the subject are substantial.

The 16 chapters of the treatise are grouped into three sections: normal and aberrant hemoglobin structure and function, the sickling disorders, and thalassemia. Subject material is extensively referenced and interpreted in the light of personal experience. Chapters that are especially well written deserve brief recognition. The discussion of laboratory techniques used for the study of hemoglobin structure and synthesis is succinct and lucid, and provides the uninitiated with a critical appraisal of the relative merits, limitations, and availability of various analyses. The present state of the art of prenatal diagnosis is presented by Blanch Alter with characteristic clarity. Dennis Miller effects a logical synthesis of molecular biology and clinical hematology in a chapter devoted to unstable and functionally anomalous hemoglobins. Outstanding, too, is Temple and Kan's contemporary review of the molecular basis for the thalassemia syndromes.

Surprisingly, some aspects of the subject receive only cursory comment or are omitted altogether. For example, the molecular basis for sickling receives only superficial treatment in a chapter devoted to erythrocyte morphology. The kinetics of sickling, which are of undoubted clinical significance, are not discussed, and an interesting literature concerning irreversible sickling is all but passed over. Because therapeutic considerations are based on extensive personal experience, there is a tendency to slight insights contributed by investigators other than the authors. There is no mention of current efforts to develop clinically useful antisickling agents or of novel approaches to transfusion therapy for thalassemia. Except for the role played by the National Sickle Cell Disease Program, historical aspects of the subject are not reviewed, nor is consideration given the geographical distribution of hemoglobin disorders, population genetics, or prevalence data.

The inclusion of additional illustrative material would have made the reader's task somewhat easier and certainly more enjoyable. The chapter on the molecular biology of thalassemias would have benefited from gene maps to illustrate the differences between β thalassemia, $\beta=\delta$ thalassemia, and hereditary persistence of fetal hemoglobin; and the section dealing with iron overload could use line diagrams that depict iron balance during various therapeutic manipulations. Reproductions of some electron photomicrographs are too dark to permit recognition of key structures, and some of the photomicrographs are magnified unnecessarily.

Despite these annoyances, however, the volume is both readable and authoritative. The editor has successfully circumvented the trap set for all multiauthored texts: excessive duplication of material. The overall high standard of the book assures it a place as a valuable complement to Weatherall and Clegg's *The Thalassemia Syndromes,* published in 1972. The latter is more comprehensive, the former more current. In addition, Schwartz's volume stands alone among books of its kind in its focus on the developmental aspects of the hemoglobinopathies and thalassemia.

Pediatric Otorhinolaryngology: A Review of Ear, Nose and Throat Problems in Children, edited by Basharat Jazbi, 289 pp, $24.50, New York, Appleton-Century-Crofts, 1980.

The purpose of this book is to "... acquaint pediatricians with the relatively new but important subspecialty and its general role in pediatrics ... the problems are discussed with an orientation to the role of the pediatrician or family practitioner. ..." The book is divided into three major sections (ear, nose, and throat) with chapters on deafness, vertigo, otitis and its complications, epistaxis, sinusitis, choanal atresia, airway ob-

struction, poisoning, tonsillitis and tonsillectomy, and traumatology.

I believe that the book does not fulfill its aim. In fact, the variable style of the chapters (written by multiple authors), their organization (complications and therapy often precede general description and pathogenesis), and the emphasis of the book (20 pages on epistaxis, none on pharyngitis) substantially reduce its value for the student or physician seeking an overview of pediatric otorhinolaryngology.

I am concerned about the lack of balanced presentation of much information: eg, the value of decongestants for systemic effect in therapy of otitis media is stated without qualification despite much recent data to the contrary; no distinction is made between preseptal periorbital cellulitis and orbital cellulitis; only penicillin is discussed in the chapter on treatment of acute otitis media (limited additional discussion occurs in another chapter); laryngotracheoplasty is discussed extensively but there is no discussion of the indications for or management of tracheostomy or nasotracheal intubation; dysmorphology of the face is treated superficially and anecdotally; hearing aids are mentioned in one short paragraph amongst three chapters on deafness.

Despite some chapters of high quality, the majority of this book is a hodgepodge of outdated information, personal opinions and rambling discussion. I cannot recommend it.

RICHARD H. RAPKIN, MD

Pediatric Chest Roentgenology: Recognizing the Abnormal, by Webster R. Riggs, Jr, 296 pp, with illus, $37.50, St Louis, Warren H Green Inc, 1979.

This book of nearly 300 pages is intended as an introduction to pediatric chest roentgenology. In chapter 1, the technique of the roentgenographic examination of the chest is illustrated and described, and complementary methods listed. The author prefers the routine of upright posteroanterior and left lateral views of the chest using the Pigg-O-Stat for most infants and uncooperative small children. The device was designed by Mr J. Pigg of Le Bonheur Children's Hospital. Disturbing artifacts produced by the holder margins are illustrated.

In the introduction, the author details the compilation of findings in 1,000 consecutive roentgenographic examinations of the chest over a summer and a winter; that the majority of the examinations were normal motivated his emphasis on "normal chest and borderlands thereof" (chapter 3, 99 pages). Although no new findings are described, among interesting points the author offers is an explanation for the superior extension of the "oblique line" in the superior mediastinum. It probably "consists of posterior layers of pleura above the aortic arch." Many other useful and borderline findings are included.

In chapter 2, the author's philosophy, preferences, and modus operandi for roentgenographic interpretation are offered. The importance of recognizing and effectively dealing with technical imperfections and problems is included. A strong point is made for the value of initially inspecting the roentgenograms unbiased by clinical information. However, for the experienced radiologist, the correlation of other findings with the roentgenographic findings and their interpretation is necessarily biased for the most intelligent opinion. The experience and developed wisdom of the radiologist should be such that he holds his own even in the presence of other biasing influences. The initial inspection and recognition of findings is most important in the training of the radiologist. It probably is less important than the correlative function for the practicing radiologist.

Slightly more than half of the book, chapters 4 through 7, is about the "recognition of the basic departures from normal," findings relevant to the questions "Is there pneumonia? Is there hyperinflation? Is there heart disease?" Again, there are no new concepts, but the text is lucidly and accurately written. In chapter 7, the most commonly encountered abnormalities are presented in the format of a "real life" reading room consultation with the medical student, the resident, the pediatrician, and the radiologist. This scenario is rather folksy and perhaps a little too cavalier for a textbook format, but important diagnostic points for each condition are included.

Overall, there are three photographs and 230 roentgenograms, mostly of adequate if not superior quality. Many only faintly show abnormalities. The references are recent and basic, but not comprehensive.

This book is intended for pediatricians and the general radiologists, but it may be even more valuable as an introductory text for medical students and residents. The author's concepts are sound and he has succeeded in providing a useful introductory text.

Carbohydrate Metabolism in Pregnancy and the Newborn 1978, edited by Hamish W. Sutherland and John M. Stowers, 540 pp, $32.50, Secaucus, NJ, Springer-Verlag New York Inc, 1979.

This text is a transcription of the second Aberdeen Colloquium, the theme of which titles this book. There are nine general categories, all of which are further subdivided into three to five chapters, ranging from intermediary metabolism of pregnancy to fetal macrosomia to asymptomatic diabetes. The scope of subject matter encompassed is broad and impressive and, almost by necessity, discursive. For example, a chapter devoted to aminoacids and the fetal development of beta cells is immediately followed by the role of glucagon in neonatal hypocalcemia. Despite the title's intimation, *newborn* carbohydrate metabolism is barely addressed but, notwithstanding, the book abounds with discussions of *fetal* metabolism and nutrition. Some sections are almost entirely clinically oriented; for instance, those on the detection of chemical gestational diabetes and the management of maternal diabetes in pregnancy.

Each chapter is well written and sufficiently referenced, ending with the authors' concise summary or comment. This is clearly a reference book for the subspecialist interested in the most recent experimental and clinical advances on the metabolic and somatic adaptations to normal pregnancy, and in particular, the perturbations of the maternal-fetal unit created by diabetes.

You can help the ADD* child with Cylert
(pemoline)

Day-long behavior therapy without dosing problems at school

Impressive all-day control.

Cylert works extremely well, given an adequate period of trial. Single daily doses are as effective for behavior control as multiple doses of methylphenidate or amphetamines. Blood levels are well sustained, without necessity for multidose administration.

No troublesome midday dose.

Cylert avoids problems of taking a drug at school. No involvement of school personnel. No peer teasing about noon-time dosing. The parents manage all medication, and the child carries no drugs. (And note that Cylert is Schedule IV, not II.)

Cylert® (pemoline) C IV

18.75, 37.5, 75 mg tablets; 37.5 mg chewables

Just once a day. At home.

*ADD: Attention Deficit Disorder (formerly called MBD, Minimal Brain Dysfunction), or the Hyperkinetic Syndrome. Please see next page for Brief Summary.

ABBOTT

9083319

Cylert® (pemoline)

DESCRIPTION: CYLERT (pemoline) is a central nervous system stimulant. Pemoline is structurally dissimilar to the amphetamines and methylphenidate.

It is an oxazolidine compound and is chemically identified as 2-amino-5-phenyl-2-oxazolin-4-one.

Pemoline is a white, tasteless, odorless powder, relatively insoluble (less than 1 mg./ml.) in water, chloroform, ether, acetone, and benzene; its solubility in 95% ethyl alcohol is 2.2 mg./ml.

CYLERT (pemoline) is supplied as tablets for oral administration.

CLINICAL PHARMACOLOGY: CYLERT (pemoline) has a pharmacological activity similar to that of other known central nervous system stimulants; however, it has minimal sympathomimetic effects. Although studies indicate that pemoline may act in animals through dopaminergic mechanisms, the exact mechanism and site of action of the drug in man is not known.

There is neither specific evidence which clearly establishes the mechanism whereby CYLERT produces its mental and behavioral effects in children, nor conclusive evidence regarding how these effects relate to the condition of the central nervous system.

The serum half-life of pemoline is approximately 12 hours. Peak serum levels of the drug occur within 2 to 4 hours after ingestion of a single dose. Multiple dose studies in adults at several dose levels indicate that steady state is reached in approximately 2 to 3 days.

Metabolites of pemoline include pemoline conjugate, pemoline dione, mandelic acid, and unidentified polar compounds. CYLERT is excreted primarily by the kidneys; approximately 75% of an oral dose is recovered in the urine within 24 hours. Approximately 43% of pemoline is excreted unchanged.

CYLERT (pemoline) has a gradual onset of action. Using the recommended schedule of dosage titration, significant clinical benefit may not be evident until the third or fourth week of drug administration.

INDICATIONS: CYLERT is indicated as an integral part of a total treatment program which typically includes other remedial measures (psychological, educational, social) for a stabilizing effect in children with a behavioral syndrome characterized by the following group of developmentally inappropriate symptoms: moderate to severe distractibility, short attention span, hyperactivity, emotional lability, and impulsivity. The diagnosis of this syndrome should not be made with finality when these symptoms are only of comparatively recent origin. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of central nervous system dysfunction may or may not be warranted.

Attention Deficit Disorder and Hyperkinetic Syndrome are among the terms being used to describe the above signs and symptoms. In the past, a variety of terms has been associated with these signs and symptoms, including: Minimal Brain Dysfunction, Hyperkinetic Reaction of Childhood, Hyperkinetic Syndrome, Hyperactive Child Syndrome, Minimal Brain Damage, Minimal Cerebral Dysfunction, and Minor Cerebral Dysfunction.

CONTRAINDICATIONS: CYLERT (pemoline) is contraindicated in patients with known hypersensitivity or idiosyncrasy to the drug. (See ADVERSE REACTIONS.)

WARNINGS: CYLERT is not recommended for children less than 6 years of age since its safety and efficacy in this age group have not been established.

Clinical experience suggests that in psychotic children, administration of CYLERT may exacerbate symptoms of behavior disturbance and thought disorder.

Data are inadequate to determine whether chronic administration of CYLERT may be associated with growth inhibition; therefore, growth should be monitored during treatment.

PRECAUTIONS: Drug treatment is not indicated in all cases of the behavioral syndrome characterized by moderate to severe distractibility, short attention span, hyperactivity, emotional lability and impulsivity. It should be considered only in light of the complete history and evaluation of the child. The decision to prescribe CYLERT should depend on the physician's assessment of the chronicity and severity of the child's symptoms and their appropriateness for his/her age. Prescription should not depend solely on the presence of one or more of the behavioral characteristics.

When these symptoms are associated with acute stress reactions, treatment with CYLERT is usually not indicated.

Long-term effects of CYLERT in children have not been well established.

Liver function tests should be performed prior to and periodically during therapy with CYLERT. The drug should be discontinued if abnormalities are revealed and confirmed by follow-up tests. (See ADVERSE REACTIONS regarding reports of abnormal liver function tests and jaundice.)

CYLERT should be administered with caution to patients with significantly impaired hepatic or renal function.

The interaction of CYLERT with other drugs has not been studied in humans. Patients who are receiving CYLERT concurrently with other drugs, especially drugs with CNS activity, should be monitored carefully.

CYLERT failed to demonstrate a potential for self-administration in primates. However, the pharmacologic similarity of pemoline to other psychostimulants with known dependence liability suggests that psychological and/or physical dependence might also occur with CYLERT. There have been isolated reports of transient psychotic symptoms occurring in adults following the long-term misuse of excessive oral doses of pemoline. CYLERT should be given with caution to emotionally unstable patients who may increase the dosage on their own initiative.

Usage during Pregnancy and Lactation: The safety of CYLERT (pemoline) for use during pregnancy and lactation has not been established.

Studies in rats have shown an increased incidence of stillbirths and cannibalization when pemoline was administered at a dose of 37.5 mg./kg./day. Postnatal survival of offspring was reduced at doses of 18.75 and 37.5 mg./kg./day.

ADVERSE REACTIONS: Insomnia is the most frequently reported side effect of CYLERT; it usually occurs early in therapy, prior to an optimum therapeutic response. In the majority of cases it is transient in nature or responds to a reduction in dosage.

Anorexia with weight loss may occur during the first weeks of therapy. In the majority of cases it is transient in nature; weight gain usually resumes within three to six months.

Stomach ache, skin rashes, increased irritability, mild depression, nausea, dizziness, headache, drowsiness, and hallucinations have been reported.

Elevations of SGOT, SGPT, and serum LDH have occurred in patients taking CYLERT, usually after several months of therapy. These effects appear to be reversible upon withdrawal of the drug, and are thought to be manifestations of a delayed hypersensitivity reaction. There have also been a few reports of jaundice occurring in patients taking CYLERT; a causal relationship between the drug and this clinical finding has not been established.

The following CNS effects have been reported with the use of CYLERT: dyskinetic movements of the tongue, lips, face and extremities, nystagmus and nystagmoid eye movements, and convulsive seizures. A definite causal relationship between CYLERT and these reactions has not been established.

Mild adverse reactions appearing early during the course of treatment with CYLERT often remit with continuing therapy. If adverse reactions are of a significant or protracted nature, dosage should be reduced or the drug discontinued.

OVERDOSAGE: Signs and symptoms of acute CYLERT overdosage may include agitation, restlessness, hallucinations, dyskinetic movements and tachycardia. The treatment for an acute overdosage of pemoline is essentially the same as that for an overdosage of any CNS stimulant. Management is primarily symptomatic and may include induction of emesis or gastric lavage, sedation, and other appropriate supportive measures.

Results of studies in dogs indicate that extracorporeal hemodialysis may be useful in the management of CYLERT overdosage; forced diuresis and peritoneal dialysis appear to be of little value.

DOSAGE AND ADMINISTRATION: CYLERT (pemoline) is administered as a single oral dose each morning. The recommended starting dose is 37.5 mg./day. This daily dose should be gradually increased by 18.75 mg. at one week intervals until the desired clinical response is obtained. The effective daily dose for most patients will range from 56.25 to 75 mg. The maximum recommended daily dose of pemoline is 112.5 mg.

Clinical improvement with CYLERT is gradual. Using the recommended schedule of dosage titration, significant benefit may not be evident until the third or fourth week of drug administration.

Where possible, drug administration should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued therapy.

PAIN GONE

while the antibiotic gets going

An effective adjuvant to systemic antibiotic treatment, AURALGAN promptly relieves the pain and reduces the inflammation of acute otitis media, while the antibiotic of choice fights the infection.

AURALGAN contains the topical analgesic action of benzocaine and antipyrine plus glycerin dehydrated...a decongestant so hygroscopic that it "blots up" excess moisture through the tympanic membrane, for relief of pressure and pain in the middle ear.

BRIEF SUMMARY
(For full prescribing information, see package circular.)
AURALGAN® Otic Solution
Each ml contains:

Antipyrine	54.0 mg
Benzocaine	14.0 mg
Glycerin dehydrated q.s. to	1.0 ml

(contains not more than 1.0% moisture) (also contains oxyquinoline sulfate)

INDICATIONS: *Acute otitis media of various etiologies*
—prompt relief of pain and reduction of inflammation in the congestive and serous stages
—adjuvant therapy during systemic antibiotic administration for resolution of the infection

CONTRAINDICATIONS: Hypersensitivity to any of the components or substances related to them. / In the presence of spontaneous perforation or discharge.

DOSAGE AND ADMINISTRATION: *Acute otitis media:* Instill AURALGAN, permitting the solution to run along the wall of the canal until it is filled. Avoid touching the ear with dropper. Then moisten a cotton pledget with AURALGAN and insert into meatus. Repeat every one to two hours until pain and congestion are relieved.

HOW SUPPLIED: No.1000—AURALGAN® Otic Solution, in package containing 15 ml (½ fl oz) bottle with separate dropper-screw cap attachment.

...in acute otitis media

Auralgan®

OTIC SOLUTION

FULLY COMPATIBLE WITH SYSTEMIC ANTIBACTERIAL THERAPY. ON PRESCRIPTION ONLY.

Ayerst AYERST LABORATORIES New York, N.Y. 10017

i-Soyalac and Soyalac are second best only to Mother's milk.

Like mother's milk, they are well-balanced formulas containing the essential nutrients all babies need. That's why doctors recommend their use as a supplement to breast feeding on those occasions when a mother is unable to breast feed.

Soyalac is the original soy-based infant formula and it's still the only one made from the extract of the whole soybean. It is easily digested, and because it is a completely milk-free product, it minimizes symptoms such as colic, diarrhea and other sensitivities to cow's milk.

We also make i-Soyalac for babies with special sensitivity problems. It is entirely free not only from cow's milk, but also from corn derivatives, and its soy carbohydrate content is insignificant.

i-Soyalac and Soyalac are available in concentrate, ready-to-serve and powder forms.

Why upset a feverish child's stomach with aspirin?

A child's complaints of nausea and stomachache may be a consequence of aspirin therapy. It has been clinically documented that therapeutic doses of aspirin may cause G.I. problems ranging from minor upset[1-3] to serious, but less frequent, ulceration and gastric hemorrhage.[4,5]

Why complicate fever therapy with gastric problems? With Children's TYLENOL you can effectively reduce his fever with virtually no G.I. risk.[6,7]

Advertising and Subscription Information

ADVERTISING OFFICES: New York: 600 Third Ave, Suite 700, New York, NY 10016 (**Manager:** Robert C. Corcoran [212-867-6640]; **Representatives:** Richard M. Johnson, John L. Reeves); **Chicago:** 535 N Dearborn St, Chicago, IL 60610 (**Manager:** Thomas J. Carroll [312-751-6675]; **Representatives:** William J. Healy, John T. Kroon); **Newport Beach, Calif:** 1940 16th St, Suite 0-206, Newport Beach, CA 92663 (**Representative:** Anton Media Associates [714-646-9090]).

Advertising Principles: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request.

Subscription Rates: The yearly rates for the AMERICAN JOURNAL OF DISEASES OF CHILDREN is as follows: for members of the AMA, $1.50, included in the annual membership dues; for nonmembers, $24 for one year, $40 for two years in the United States and US possessions; all other countries, $34 for one year, $60 for two years. Special yearly price to residents, interns, and medical students in the United States and US possessions, one year, $12; two years, $20. Address all subscription communications to Circulation-Fulfillment Department. Phone: 312, 751-6079.

Change of Address: POSTMASTER, send address changes to Helen R. Mazur, Director, Circulation-Fulfillment. Notification of address changes should be sent at least six weeks in advance, including both old and new address, and a mailing label taken from the most recent copy. Include your new zip code number.

AMERICAN JOURNAL OF DISEASES OF CHILDREN (ISSN 0002-922X) is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago and at additional mailing office.

Filling a need since 1927

"In offering Similac to the Medical Profession we do so with the thought in mind that breast milk is nature's food for the infant, but as many infants are deprived of their natural food, either wholly or in part, some form of nourishment must be substituted, and Similac is offered as this substitute."

The above statement appeared in medical journals in the announcement of the introduction of Similac® Infant Formulas in 1927. Today, as then, we continue to recognize and support breast-feeding as the ideal feeding for infants.

Over the years, Ross Laboratories has promoted and supported breast-feeding by providing health professionals with service materials and patient counseling literature.

However, it should be recognized that not all infants will be breast-fed throughout the first year of life. Similac With Iron is offered for your consideration as a better alternative than cow milk if the mother discontinues breast-feeding early, if a supplement to breast-feeding is needed, or if breast-feeding is not adopted.

Our objective is to provide an appropriate infant feeding for those instances when an infant does not receive breast milk. We are proud of Similac Infant Formulas and are proud to have filled a need for high quality infant feeding for over 50 years.

Filling a need today

Septra® Suspension b.i.d.
Each teaspoonful (5 ml) contains: 40 mg trimethoprim and 200 mg sulfamethoxazole
a consistent performer in treating acute otitis media due to susceptible organisms.
Wellcome
Burroughs Wellcome Co.
Research Triangle Park
North Carolina 27709

IN PEDIATRIC INFECTIONS•

A powerful antibacterial performance

The efficacy of Septra has been substantiated in a study of 94 children with acute otitis media due to *H influenzae* and/or *S pneumoniae (D pneumoniae)*. After 10 days' therapy with trimethoprim/sulfamethoxazole (TMP/SMX), the cure rate was 95.7%.[1*]

A powerful performance against ampicillin-resistant *H influenzae*†

In another study of 16 children (aged 5–38 months) with purulent otitis media caused by *H influenzae*, it was noted that 10 days' therapy with ampicillin or amoxicillin produced no response in 14 patients. However, after 10 days' therapy with TMP/SMX, 93% of the 14 children responded favorably.[2] Additional *in vitro* studies have shown that when over 200 isolates of ampicillin-resistant *H influenzae* were tested, all proved susceptible to TMP/SMX.[1]

A powerful "double-blockade" method of performing

Septra interferes with or hinders bacterial folate metabolism at two sequential points. This "double-blockade" action is believed to potentiate the effect of the component agents against sensitive bacteria.[3]

Please note, Septra is not recommended for the treatment of streptococcal pharyngitis. It is contraindicated during pregnancy and lactation, in patients hypersensitive to its components and infants under 2 months of age.

To date, there are limited data on the safety of repeated use of Septra in children under two years of age. Septra is not indicated for prophylactic or prolonged administration in otitis media at any age.

In vitro data do not necessarily correlate with clinical results.
*The criteria for success were (1) significant clinical response at 72 hours (2) all signs and symptoms normal at day 24.
†To date, clinical data on the effectiveness of Septra in the treatment of acute otitis media due to *H influenzae* with *in vitro* resistance to ampicillin and *in vitro* sensitivity to Septra are limited.

And a powerful plus of good taste

See prescribing information on the next page

The original pleasant tasting, cherry-flavored

Septra® Suspension b.i.d.

Each teaspoonful (5 ml) contains: 40 mg trimethoprim and 200 mg sulfamethoxazole

A consistent performer in treating acute otitis media due to susceptible organisms.

Septra® DS b.i.d.

Each tablet contains: 160 mg trimethoprim and 800 mg sulfamethoxazole

Septra® DS Tablets Double Strength
Septra® Tablets
Septra® Suspension

INDICATIONS AND USAGE:
URINARY TRACT INFECTIONS: **For the treatment of urinary tract infections due to susceptible strains of the following organisms:** *Escherichia coli, Klebsiella-Enterobacter, Proteus mirabilis, Proteus vulgaris, Proteus morganii.* **It is recommended that initial episodes of uncomplicated urinary tract infections be treated with a single effective antibacterial agent rather than the combination.**

NOTE: Currently, the increasing frequency of resistant organisms is a limitation of the usefulness of all antibacterial agents, especially in the treatment of these urinary tract infections.

ACUTE OTITIS MEDIA: **For the treatment of acute otitis media in children due to susceptible strains of** *Haemophilus influenzae* **or** *Streptococcus pneumoniae* **when in the judgment of the physician Septra offers some advantage over the use of other antimicrobial agents. Limited clinical information is presently available on the effectiveness of treatment of otitis media with Septra when the infection is due to** *Haemophilus influenzae* **resistant to ampicillin. To date, there are limited data on the safety of repeated use of Septra in children under two years of age. Septra is not indicated for prophylactic or prolonged administration in otitis media at any age.**

SHIGELLOSIS: **For the treatment of enteritis caused by susceptible strains of** *Shigella flexneri* **and** *Shigella sonnei* **when antibacterial therapy is indicated.**

PNEUMOCYSTIS CARINII **PNEUMONITIS: For the treatment of documented** *Pneumocystis carinii* **pneumonitis. To date, this drug has been tested only in patients 9 months to 16 years of age who were immunosuppressed by cancer therapy.**

CONTRAINDICATIONS: Hypersensitivity to trimethoprim or sulfonamides. Pregnancy and during the nursing period. Infants less than two months of age.

WARNINGS: SEPTRA SHOULD NOT BE USED IN THE TREATMENT OF STREPTOCOCCAL PHARYNGITIS.

Clinical studies have documented that patients with Group A β-hemolytic streptococcal tonsillopharyngitis have a greater incidence of bacteriologic failure when treated with Septra than do those patients treated with penicillin as evidenced by failure to eradicate this organism from the tonsillopharyngeal area.

Deaths associated with administration of sulfonamides have been reported from hypersensitivity reactions, agranulocytosis, aplastic anemia and other blood dyscrasias. Experience with trimethoprim alone is much more limited, but occasional interference with hematopoiesis has been reported as well as an increased incidence of thrombopenia with purpura in elderly patients on certain diuretics, primarily thiazides.

Sore throat, fever, pallor, purpura or jaundice may be early signs of serious blood disorders. Frequent CBCs are recommended; therapy should be discontinued if a significant reduction in the count of any formed blood element is noted.

PRECAUTIONS: Use with caution in patients with impaired renal or hepatic function, possible folate deficiency, severe allergy or bronchial asthma. In glucose-6-phosphate dehydrogenase-deficient individuals, hemolysis may occur (frequently dose-related). During therapy, maintain adequate fluid intake and perform frequent urinalyses with careful microscopic examination and renal function tests, particularly where there is impaired renal function.

Since Septra may prolong prothrombin time in patients on warfarin, coagulation time should be reassessed when Septra is given.

ADVERSE REACTIONS: All major reactions to sulfonamides and trimethoprim are included, even if not reported with Septra. *Blood Dyscrasias:* Agranulocytosis, aplastic anemia, megaloblastic anemia, thrombopenia, leukopenia, hemolytic anemia, purpura, hypoprothrombinemia and methemoglobinemia. *Allergic Reactions:* Erythema multiforme, Stevens-Johnson syndrome, generalized skin eruptions, epidermal necrolysis, urticaria, serum sickness, pruritus, exfoliative dermatitis, anaphylactoid reactions, periorbital edema, conjunctival and scleral injection, photosensitization, arthralgia and allergic myocarditis. *Gastrointestinal Reactions:* Glossitis, stomatitis, nausea, emesis, abdominal pains, hepatitis, diarrhea and pancreatitis. *C.N.S. Reactions:* Headache, peripheral neuritis, mental depression, convulsions, ataxia, hallucinations, tinnitus, vertigo, insomnia, apathy, fatigue, muscle weakness and nervousness. *Miscellaneous Reactions:* Drug fever, chills and toxic nephrosis with oliguria and anuria. Periarteritis nodosa and L.E. phenomenon have occurred.

Due to certain chemical similarities to some goitrogens, diuretics (acetazolamide and the thiazides) and oral hypoglycemic agents, sulfonamides have caused rare instances of goiter production, diuresis and hypoglycemia; cross-sensitivity may exist with these agents. In rats, long-term administration of sulfonamides has produced thyroid malignancies.

DOSAGE AND ADMINISTRATION: Not recommended for use in infants less than two months of age.

URINARY TRACT INFECTIONS AND SHIGELLOSIS IN ADULTS AND CHILDREN AND ACUTE OTITIS MEDIA IN CHILDREN:

Adults: The usual adult dosage for the treatment of urinary tract infections is two tablets or four teaspoonfuls (20 ml) every 12 hours for 10 to 14 days. An identical daily dosage is used for 5 days in the treatment of shigellosis.

Children: The recommended dose for children with urinary tract infections or acute otitis media is 8 mg/kg trimethoprim and 40 mg/kg sulfamethoxazole per 24 hours, given in two divided doses every 12 hours for 10 days. An identical daily dosage is used for 5 days in the treatment of shigellosis. The following table is a guideline for the attainment of this dosage using Septra Tablets or Suspension.

Children: Two months of age or older:

Weight		Dose — every 12 hours	
lb	kg	Teaspoonfuls	Tablets
22	10	1 (5 ml)	½
44	20	2 (10 ml)	1
66	30	3 (15 ml)	1½
88	40	4 (20 ml)	2 (or 1 DS tablet)

For patients with renal impairment:

Creatinine Clearance (ml/min)	Recommended Dosage Regimen
Above 30	Usual Standard Regimen
15–30	Half of the usual dosage regimen
Below 15	Use Not Recommended

PNEUMOCYSTIS CARINII **PNEUMONITIS:**
The recommended dosage for patients with documented *Pneumocystis carinii* pneumonitis is 20 mg/kg trimethoprim and 100 mg/kg sulfamethoxazole per 24 hours given in equally divided doses every 6 hours for 14 days. The following table is a guideline for the attainment of this dosage in children.

Weight		Dose — every 6 hours	
lb	kg	Teaspoonfuls	Tablets
18	8	1 (5 ml)	½
35	16	2 (10 ml)	1
53	24	3 (15 ml)	1½
70	32	4 (20 ml)	2 (or 1 DS tablet)

HOW SUPPLIED: TABLETS, containing 80 mg trimethoprim and 400 mg sulfamethoxazole — bottles of 40, 100, 500 and 1000 tablets; unit dose pack of 100.

ORAL SUSPENSION, containing the equivalent of 40 mg trimethoprim and 200 mg sulfamethoxazole in each teaspoonful (5 ml), cherry flavored — bottle of 473 ml. Also available in double strength, oval-shaped, pink, scored tablets containing 160 mg trimethoprim and 800 mg sulfamethoxazole — Compliance™ Pak of 20, bottle of 60 and unit dose pack of 100.

Better than ever, as convenient as ever

Single-Dose Vials

M-M-R® II

(MEASLES, MUMPS AND RUBELLA VIRUS VACCINE, LIVE | MSD)

Better

contains rubella virus strain RA 27/3

Convenient

one shot vaccinates against all three: measles, mumps, rubella

For a brief summary of prescribing information, please see following page.

MSD
MERCK SHARP & DOHME

Copyright © Merck & Co., Inc., 1980
All rights reserved.

Indications: *ATTENUVAX® (Measles Virus Vaccine, Live, Attenuated, MSD)* — Active immunization against measles (rubeola) in children 15 months of age or older.

BIAVAX®II (Rubella and Mumps Virus Vaccine, Live, MSD) — Simultaneous immunization against rubella and mumps in children 15 months of age to puberty. May be given as early as 12 months if that offers greater convenience in scheduling.

MERUVAX®II (Rubella Virus Vaccine, Live, MSD) — Immunization against rubella (German measles) in children 15 months of age to puberty. May be given as early as 12 months if that offers greater convenience in scheduling. May be useful for adolescent and adult males to prevent or control rubella outbreaks in circumscribed population groups. In postpubertal females vaccination must not be undertaken unless the woman is not pregnant, is susceptible to rubella (as shown by Hemagglutination Inhibition test), agrees not to become pregnant for next three months (also in immediate postpartum period), and is informed of frequent occurrence of self-limited arthralgia and possible arthritis beginning two to four weeks after vaccination.

M-M-R®II (Measles, Mumps and Rubella Virus Vaccine, Live, MSD) — Simultaneous immunization against measles, mumps, and rubella in children 15 months of age to puberty.

M-R-VAX®II (Measles and Rubella Virus Vaccine, Live, MSD) — Simultaneous immunization against measles (rubeola) and rubella (German measles) in children 15 months of age to puberty.

MUMPSVAX® (Mumps Virus Vaccine, Live, MSD) — Immunization against mumps for children 15 months of age or older and adults. May be given as early as 12 months if that offers greater convenience in scheduling.

Contraindications: Pregnancy or the possibility of pregnancy within three months following vaccination (see special considerations for ATTENUVAX below); hypersensitivity to neomycin; any febrile respiratory illness or other active infection; for measles-containing vaccines, active untreated tuberculosis; therapy with ACTH, corticosteroids (except as replacement therapy, e.g., for Addison's disease), irradiation, alkylating agents, or antimetabolites; blood dyscrasias, leukemia, lymphomas of any type, or other malignant neoplasms affecting the bone marrow or lymphatic systems; primary immunodeficiency states, including cellular immune deficiencies, hypogammaglobulinemic and dysgammaglobulinemic states.

Hypersensitivity to Eggs, Chicken, or Chicken Feathers: For measles- and/or mumps-containing vaccines, in patients hypersensitive to eggs, chicken, or chicken feathers, weigh benefits of immunization against potential risks of hypersensitivity reactions.

Pregnancy: *ATTENUVAX* — The effects of ATTENUVAX on fetal development are unknown at this time. Live attenuated measles virus vaccine should not be given to persons known to be pregnant; furthermore, pregnancy should be avoided for three months following vaccination. Reports have indicated that natural measles during pregnancy enhances fetal risk. Increased rates of spontaneous abortion, stillbirth, congenital defects, and prematurity have been observed subsequent to natural measles during pregnancy. There are no adequate studies of the attenuated (vaccine) strain of measles virus in pregnancy. However, it would be prudent to assume that the vaccine strain of virus is also capable of inducing adverse fetal effects for up to three months following vaccination.

Vaccine administration to postpubertal females entails a potential for inadvertent immunization during pregnancy. Theoretical risks involved should be weighed against the risks that measles poses to the unimmunized adolescent or adult. Advisory committees reviewing this matter have recommended vaccination of postpubertal females who are presumed to be susceptible to measles and not known to be pregnant. If a measles exposure occurs during pregnancy, one should consider the possibility of providing temporary passive immunity through the administration of immune serum globulin (human).

Precautions: Administer subcutaneously; *do not give intravenously.* Epinephrine should be available for immediate use should an anaphylactoid reaction occur. Should not be given less than one month before or after immunization with other *live* virus vaccines, with the exception that ATTENUVAX, MUMPSVAX, and/or MERUVAX II may be administered simultaneously. BIAVAX II may be administered simultaneously with ATTENUVAX. Monovalent or trivalent poliovirus vaccine, live, oral, may be administered simultaneously with ATTENUVAX and/or MUMPSVAX. Vaccinations should be deferred for at least three months following blood or plasma transfusions or administration of more than 0.02 ml human immune serum globulin per pound of body weight. However, rubella vaccine may be given prior to discharge to susceptible postpartum patients who received blood products, provided that a repeat HI titer is drawn six to eight weeks after vaccination to insure seroconversion; similarly, although rubella vaccine may be given in the immediate postpartum period to those nonimmune women who have received anti-Rh_o (D) immune globulin (human) without interfering with vaccine effectiveness, a follow-up postvaccination HI titer should also be determined.

Attenuated measles, mumps, and rubella virus vaccines, live, given separately, may result in a temporary depression of tuberculin skin sensitivity; therefore, if a tuberculin test is to be done, it should be administered before or simultaneously with any of these virus vaccines. Vaccination may not result in seroconversion in 100 percent of susceptible subjects.

Measles-Containing Vaccines — Due caution should be employed in children with a history of febrile convulsions, cerebral injury, or any other condition in which stress due to fever should be avoided. The physician should be alert to the temperature elevation which may occur 5 to 12 days after vaccination. The occurrence of thrombocytopenia and purpura has been extremely rare.

Rubella-Containing Vaccines — Excretion of live attenuated rubella virus from the nose and throat has occurred in the majority of susceptible individuals 7 to 28 days after vaccination. There is no confirmed evidence to indicate that such virus is transmitted to susceptible persons who are in contact with vaccinated individuals. Consequently, transmission, while accepted as a theoretical possibility, is not regarded as a significant risk.

Adverse Reactions: To date, clinical evaluation of the combination vaccines has revealed those adverse reactions expected to follow administration of the monovalent vaccines given separately.

Measles-Containing Vaccines — Occasionally, moderate fever (101–102.9 F); less commonly, high fever (above 103 F); rarely, febrile convulsions. Infrequently, rash, usually minimal without generalized distribution. Reactions at injection site. Local reactions characterized by marked swelling, redness, and vesiculation at the injection site of attenuated live measles virus vaccines have occurred in children who previously received killed measles vaccine; the combination vaccines were not given under this condition in clinical trials.

Experience from more than 80 million doses of all live measles vaccines given in the U.S. through 1975 indicates that significant central nervous system reactions such as encephalitis and encephalopathy, occurring within 30 days after vaccination, have been temporally associated with measles vaccine approximately once for every million doses. In no case has it been shown that reactions were actually caused by vaccine. The Center for Disease Control has pointed out that "a certain number of cases of encephalitis may be expected to occur in a large childhood population in a defined period of time even when no vaccines are administered." However, the data suggest the possibility that some of these cases may have been caused by measles vaccines. The risk of such serious neurological disorders following live measles virus vaccine administration remains far less than that for encephalitis and encephalopathy with natural measles (one per thousand reported cases). There have been reports of subacute sclerosing panencephalitis (SSPE) in children who did not have a history of natural measles but did receive measles vaccine. Some of these cases may have resulted from unrecognized measles in the first year of life or possibly from the measles vaccination. Based on estimated nationwide measles vaccine distribution, the association of SSPE cases to measles vaccination is about one case per million vaccine doses distributed, far less than the 5 to 10 cases of SSPE per million cases of natural measles.

Rubella-Containing Vaccines — Adverse reactions include malaise, sore throat, headache, fever, and rash; mild local reactions such as erythema, local pain, induration, tenderness, and regional lymphadenopathy; thrombocytopenia and purpura; allergic reactions such as urticaria; and arthritis, arthralgia that is infrequently associated with signs of inflammation, and polyneuritis.

Moderate fever (101–102.9 F) occurs occasionally, and high fever (103 F) occurs less commonly. Rash occurs infrequently and is usually minimal without generalized distribution. Encephalitis and other nervous system reactions have occurred very rarely.

Transient arthritis, arthralgia, and polyneuritis vary in frequency and severity with age and sex, being greatest in adult females and least in prepubertal children. In children, joint reactions are rare and of brief duration if they do occur. In women, incidence rates for arthritis and arthralgia are generally higher than those seen in children (children: 0–3 percent; women: 12–20 percent), and the reactions tend to be more marked and of longer duration. Rarely, symptoms may persist for a matter of months. In adolescent girls, the reactions appear to be intermediate in incidence between those seen in children and in adult women. Even in older women (35–45 years), these reactions are generally well tolerated and rarely interfere with normal activities.

Mumps-Containing Vaccines — Parotitis and orchitis. Rarely, purpura and allergic reactions such as urticaria. Very rarely, encephalitis and other nervous system reactions. With the monovalent mumps vaccine, mild fever occurs occasionally, and fever above 103 F is uncommon.

Shipment, Storage, and Reconstitution: During shipment, to insure that there is no loss of potency, the vaccine must be maintained at a temperature of 10 C (50 F) or less. Before reconstitution, store vaccines at 2–8 C (35.6–46.4 F) and *protect from light.* Use only diluent supplied to reconstitute vaccines. If not used immediately, store reconstituted vaccines in a dark place at 2–8 C (35.6–46.4 F), and discard if not used within eight hours. Use a separate sterile syringe and needle for each individual patient to prevent transmission of infectious agents from one person to another.

Color: The color of the vaccine when reconstituted is yellow. ATTENUVAX is acceptable for use only if clear.

How Supplied: *ATTENUVAX® (Measles Virus Vaccine, Live, Attenuated, MSD)* — Single-dose vials of lyophilized vaccine, containing when reconstituted not less than the equivalent of 1,000 $TCID_{50}$ (tissue culture infectious doses) of measles virus vaccine expressed in terms of the assigned titer of the FDA Reference Measles Virus, and approximately 25 mcg neomycin.

BIAVAX®II (Rubella and Mumps Virus Vaccine, Live, MSD) — Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than 1,000 $TCID_{50}$ of rubella virus vaccine, live, and 5,000 $TCID_{50}$ of mumps virus vaccine, live, expressed in terms of the assigned titer of the FDA Reference Rubella and Mumps Viruses, and approximately 25 mcg neomycin.

MERUVAX®II (Rubella Virus Vaccine, Live, MSD) — Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than the equivalent of 1,000 $TCID_{50}$ of rubella virus vaccine expressed in terms of the assigned titer of the FDA Reference Rubella Virus, and approximately 25 mcg neomycin.

M-M-R®II (Measles, Mumps and Rubella Virus Vaccine, Live, MSD) — Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than 1,000 $TCID_{50}$ of measles virus vaccine, live, attenuated, 5,000 $TCID_{50}$ of mumps virus vaccine, live, and 1,000 $TCID_{50}$ of rubella virus vaccine, live, expressed in terms of the assigned titer of the FDA Reference Measles, Mumps, and Rubella Viruses, and approximately 25 mcg neomycin.

M-R-VAX®II (Measles and Rubella Virus Vaccine, Live, MSD) — Single-dose vials of lyophilized vaccine, 0.5 ml when reconstituted as directed and containing not less than 1,000 $TCID_{50}$ of measles virus vaccine, live, attenuated, and 1,000 $TCID_{50}$ of rubella virus vaccine, live, expressed in terms of the assigned titer of the FDA Reference Measles and Rubella Viruses, and approximately 25 mcg neomycin.

MUMPSVAX® (Mumps Virus Vaccine, Live, MSD) — Single-dose vials of lyophilized vaccine, containing when reconstituted not less than 5,000 $TCID_{50}$ of mumps virus vaccine expressed in terms of the assigned titer of the FDA Reference Mumps Virus, and approximately 25 mcg neomycin.

Each of these vaccines is supplied as a single-dose vial with a disposable syringe containing diluent and fitted with a 25-gauge, ⅝" needle, and as a box of 10 single-dose vials with an accompanying box of 10 diluent-containing disposable syringes with affixed needles.

Instructions for Authors

General Information.—Send manuscripts by first-class (**not** registered) mail to the Chief Editor, Gilbert B. Forbes, MD, Box 777, 601 Elmwood Ave, Rochester, NY 14642. Designate one author as correspondent and provide his/her address and telephone number. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the *American Journal of Diseases of Children* and may not be published elsewhere without permission from the publisher (AMA).

In view of the provisions of *The Copyright Revision Act of 1976*, effective Jan 1, 1978, the author(s) of manuscripts, letters to the editor, and book reviews accepted for publication in the JOURNAL will be required to sign and date the following statement: "In consideration of the AMA taking action in reviewing and editing my/our submission, the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the AMA in the event that such work is published by the AMA."

Manuscript Preparation.—All the elements of a manuscript must be submitted in **triplicate, double-spaced throughout**. Use heavy-duty white bond paper, 21.6 × 27.9 cm, and 2.5-cm margins. If a word processor is used, do not justify lines. The style of writing should conform to proper English usage and syntax. All measurements are to be in metric units, temperatures in Centigrade.

All accepted manuscripts are subject to copy editing. The corresponding author will receive an edited typescript and layout for approval. Forms for ordering reprints are included with the edited typescript. Proofs will be sent for approval if requested by the author and if printing deadlines permit. The author is responsible for all statements in his/her work, including changes made by the copy editor.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines. The title page should include the full names and academic affiliations of all authors, the address to which requests for reprints should be sent, and, if the manuscript was presented at a meeting, the name of the organization, place, and date on which it was read.

Abstract.—Provide an abstract (135-word maximum) of the article, including statement of the problem, method of study, results, and conclusions. The abstract replaces the summary.

Informed Consent.—Manuscripts reporting the results of experimental investigations on humans must include a statement to the effect that informed consent was obtained from the parents or guardians after the nature of the procedure(s) had been fully explained.

Clinical Memoranda.—Brief accounts of interesting observations and clinical situations. Limited to 800 words plus one table or illustration; abstract unnecessary. Submit in triplicate, double-spaced. Copyright assignment required.

Letters to the Editor.—Correspondence pertaining to material published in the JOURNAL. Limit 500 words. Submit in triplicate, double-spaced, and clearly marked "For publication." Copyright assignment required.

References.—List in order of their appearance in the text, and type double-spaced, in the following manner:

1. Applebaum MM, Thaler MM: Reye syndrome without initial hepatic involvement. *Am J Dis Child* 1977;131:295-296.

Do not include unpublished data, personal communications, or manuscripts "in preparation" or "submitted" in the list of references. Such material, if essential, may be incorporated in the body of the article.

Illustrations.—Submit only high-contrast glossy prints in triplicate, unmounted and untrimmed. Preferred size is 12.7 × 17.3 cm (5 × 7 in). Figure number, name of first author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. Lettering must be legible after reduction to column size. Magnification and stain should be provided for histologic sections.

For illustrations in full color submit 35-mm, positive color transparencies, mounted in cardboard and carefully packaged. Do not submit glass-mounted transparencies; do not submit color prints. The fee is $275 for up to six square-finished color illustrations that can be arranged on one page. A letter of intent to pay the fee must accompany submission.

Legends.—Legends for illustrations should be typed double-spaced, beginning on a separate sheet of paper (40-word maximum for each).

Acknowledgments.—Illustrations and tables from other publications must be suitably acknowledged, and accompanied by written permission from publisher and author.

Photographic Consents.—A signed statement of consent from **both** parents (or guardian) or the persons involved must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

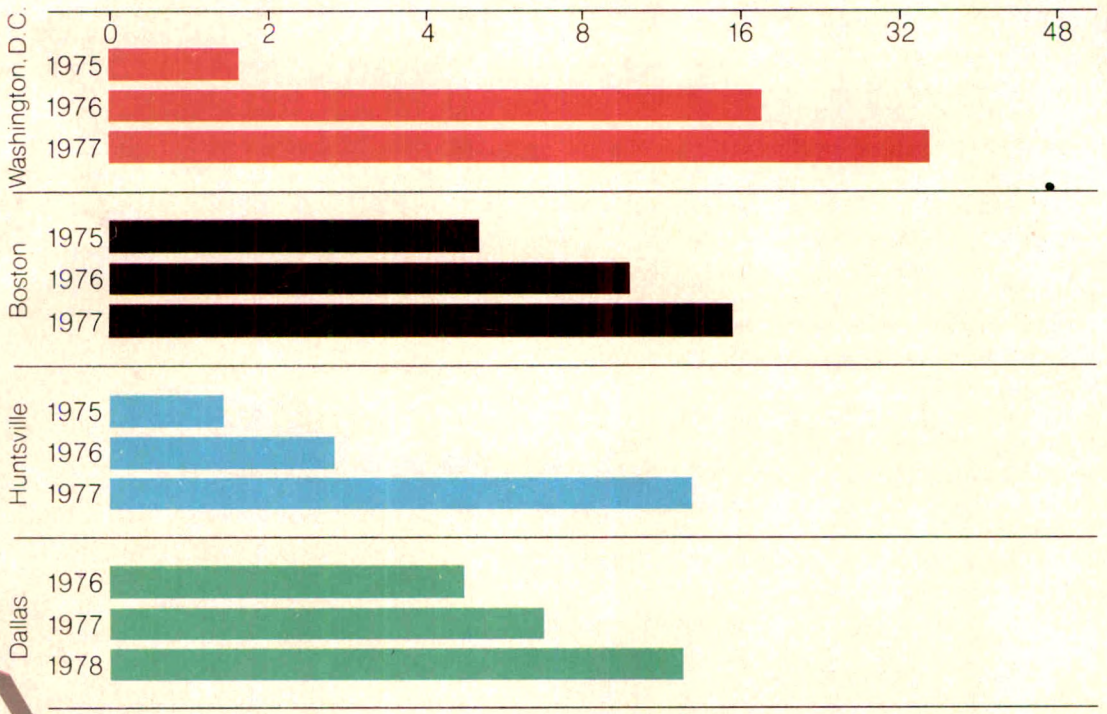
Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 21.6 × 27.9 cm paper. If a table must be continued, use a second sheet and repeat all heads. Each table must have a title.

Uniform Requirements.—Further details on manuscript preparation are given in the document *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* prepared by the International Steering Committee of Medical Editors. Reprints of this document are available by directing requests to this journal: Scientific Publications, 535 N Dearborn St, Chicago, IL 60610.

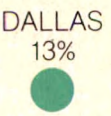
Increasing resistance of

AMPICILLIN RESISTANCE IN HAEMOPHILUS

(Percentages are ampicillin-resistant *H. influenzae* isolates*)



*Isolates obtained from a variety of body fluids (such as middle-ear exudate and blood).



Brief Summary.
Consult the package literature for prescribing information.

Indications and Usage: Ceclor*(cefaclor, Lilly) is indicated in the treatment of the following infections when caused by susceptible strains of the designated microorganisms:

Otitis media caused by *Streptococcus pneumoniae (Diplococcus pneumoniae), Haemophilus influenzae,* staphylococci, and *S. pyogenes* (group A beta-hemolytic streptococci).

Appropriate culture and susceptibility studies should be performed to determine susceptibility of the causative organism to Ceclor.

Contraindication: Ceclor is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

Warnings: IN PENICILLIN-SENSITIVE PATIENTS, CEPHALOSPORIN ANTIBIOTICS SHOULD BE ADMINISTERED CAUTIOUSLY. THERE IS CLINICAL AND LABORATORY EVIDENCE OF PARTIAL CROSS-ALLERGENICITY OF THE PENICILLINS AND THE CEPHALOSPORINS, AND THERE ARE INSTANCES IN WHICH PATIENTS HAVE HAD REACTIONS TO BOTH DRUG CLASSES (INCLUDING ANAPHYLAXIS AFTER PARENTERAL USE).

Antibiotics, including Ceclor® (cefaclor, Lilly), should be administered cautiously to any patient who has demonstrated some form of allergy, particularly to drugs.

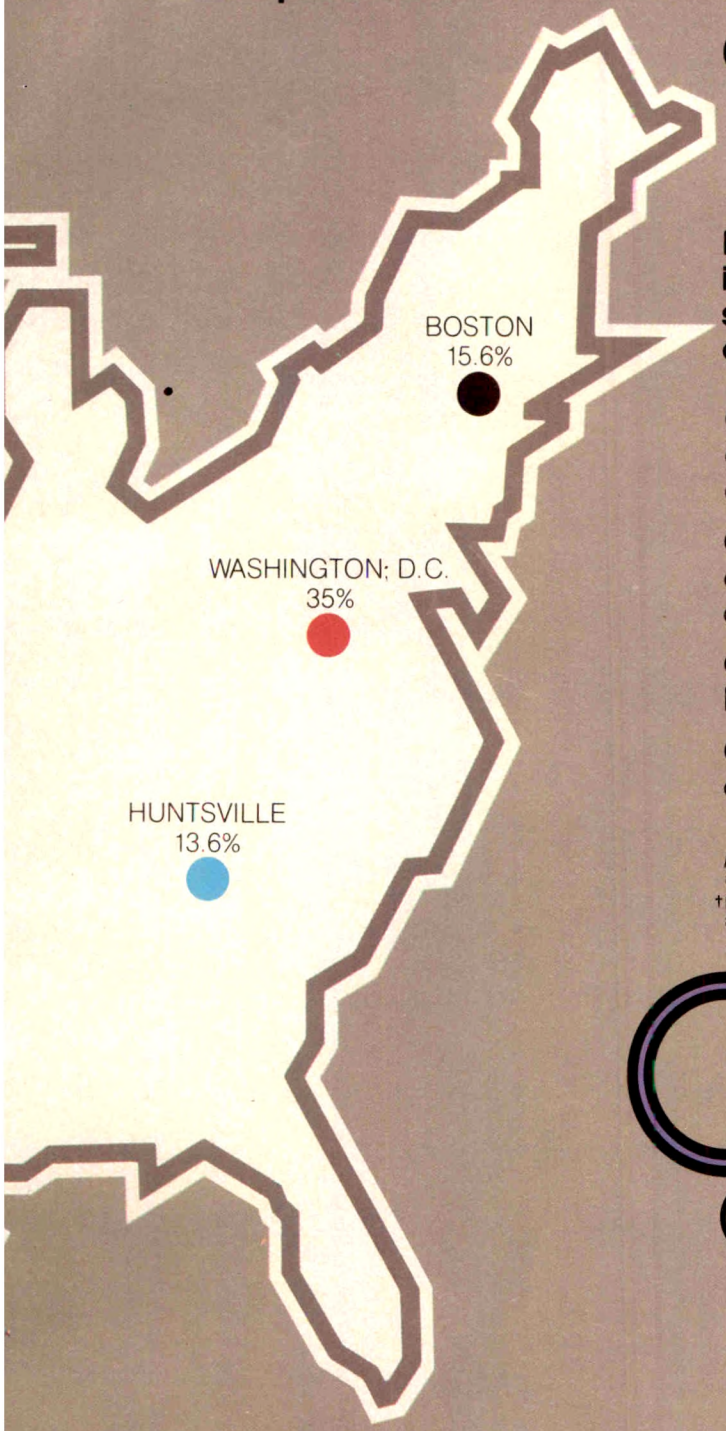
Precautions: If an allergic reaction to cefaclor occurs, the drug should be discontinued, and, if necessary, the patient should be treated with appropriate agents, e.g., pressor amines, antihistamines, or corticosteroids.

Prolonged use of cefaclor may result in the overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection occurs during therapy, appropriate measures should be taken.

Positive direct Coombs tests have been reported during treatment with the cephalosporin antibiotics. In hematologic studies or in transfusion cross-matching procedures when antiglobulin tests are performed on the minor side o in Coombs testing of newborns whose mothers have received cephalosporin antibiotics before parturition, it

Haemophilus influenzae in otitis media...

a valid concern



In many areas of the country, increasing numbers of *H. influenzae* show resistance to conventional antibiotic therapy.[1-3]

Ceclor is effective in the treatment of otitis media†, including that due to some ampicillin-resistant strains of *H. influenzae*.[4-9]

Ceclor has been shown to be clinically and bacteriologically effective in treating otitis media due to susceptible organisms.[10]

Ceclor is available in two pleasant-tasting liquids.

Ceclor provides effective single-agent antibiotic therapy for otitis media.

Note: Ceclor is contraindicated in patients with known allergy to the cephalosporins and should be given cautiously to penicillin-allergic patients.

†Due to susceptible strains of *Streptococcus pneumoniae*, *H. influenzae*, staphylococci, and *S. pyogenes*.

125-mg/5-ml and 250-mg/5-ml oral suspensions

Ceclor®

cefaclor

should be recognized that a positive Coombs test may be due to the drug.

Ceclor ® (cefaclor, Lilly) should be administered with caution in the presence of markedly impaired renal function. Under such a condition, careful clinical observation and laboratory studies should be made because safe dosage may be lower than that usually recommended.

Usage in Pregnancy—Although no teratogenic or antifertility effects were seen in reproduction studies in mice and rats receiving up to 12 times the maximum human dose or in ferrets given three times the maximum human dose, the safety of this drug for use in human pregnancy has not been established. The benefits of the drug in pregnant women should be weighed against a possible risk to the fetus.

Usage in Infancy—Safety of this product for use in infants less than one month of age has not been established.

Adverse Reactions: In clinical studies in 1493 patients, adverse effects considered related to cefaclor therapy were uncommon and are listed below:

Gastrointestinal symptoms occurred in about 2.5 percent of patients and included diarrhea (1 in 70) and nausea and vomiting (1 in 90).

Hypersensitivity reactions were reported in about 1.5 percent of patients and included morbilliform eruptions (1 in 100). Pruritus, urticaria, and positive Coombs tests each occurred in less than 1 in 200 patients.

Other effects considered related to therapy included eosinophilia (1 in 50 patients) and genital pruritus or vaginitis (less than 1 in 100 patients).

Causal Relationship Uncertain—Transitory abnormalities in clinical laboratory test results have been reported. Although they were of uncertain etiology, they are listed below to serve as alerting information for the physician.

Hepatic—Slight elevations in SGOT, SGPT, or alkaline phosphatase values (1 in 40).

Hematopoietic—Transient fluctuations in leukocyte count, predominantly lymphocytosis occurring in infants and young children (1 in 40).

Renal—Slight elevations in BUN or serum creatinine (less than 1 in 500) or abnormal urinalysis (less than 1 in 200).

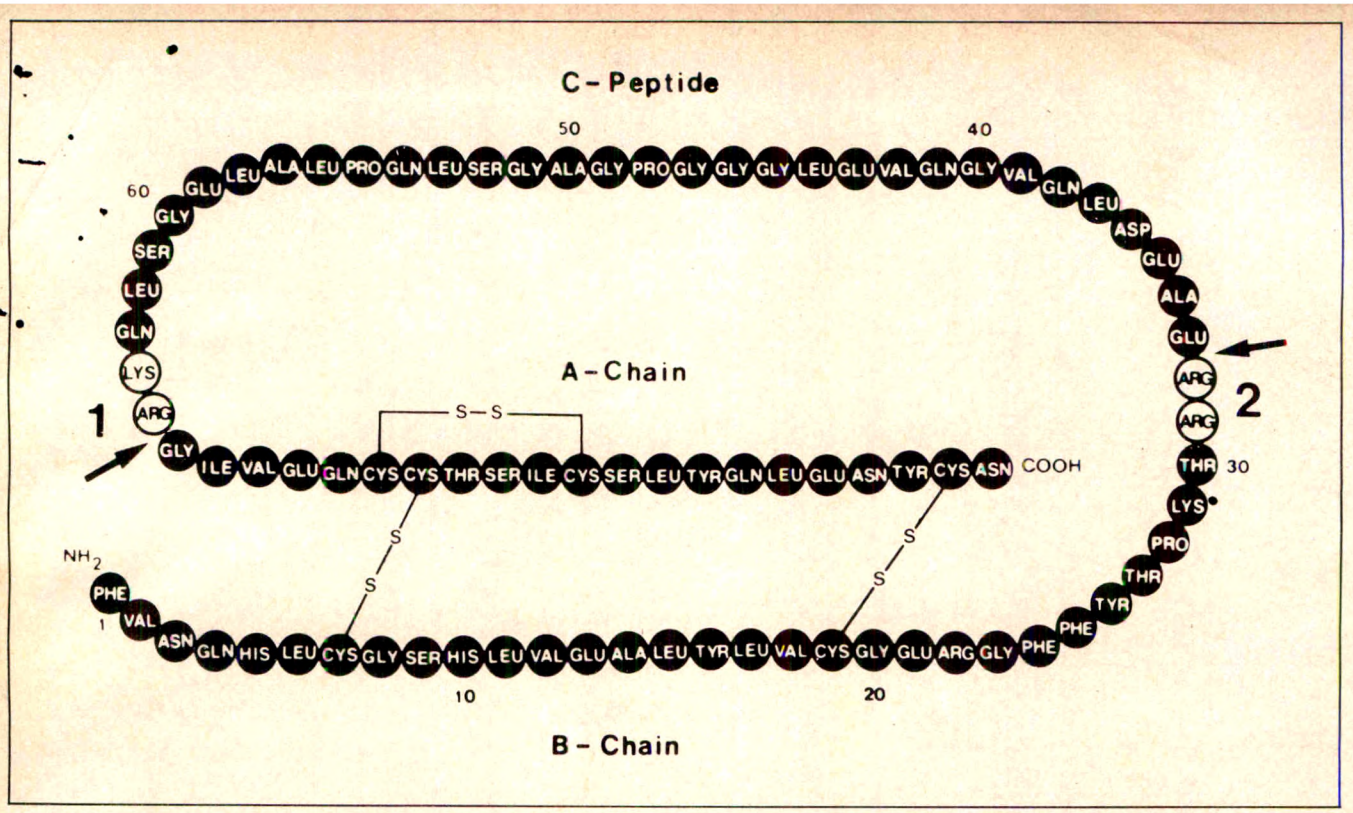
Insulin Biosynthesis and C-peptide

Practical Applications From Basic Research

The insulin molecule released into the circulation by the β cells of Langerhans' islets consists of two separate, straight polypeptide chains linked by disulfide bridges between and within the chains (Figure).[1,2] These two chains are not separately manufactured; instead, the parent molecule synthesized on the ribosome consists of a larger precursor, proinsulin, a single coiled chain in which the amide terminus of the A-chain is linked to the carboxyl terminus of the B-chain by a connecting or C-peptide (Figure).[1,2] Actually, an even larger precursor, pre-proinsulin, containing an additional peptide chain on the amino terminus of the A-chain is initially synthesized. This additional piece acts in a manner analogous to the leader in a film reel and is rapidly excised during synthesis.[1,2] Further processing of proinsulin cleaves the C-peptide consisting of 31 amino acids from the insulin molecule at the sites indicated in the figure. As might be anticipated, defects in the cleavage sites have now been identified.[3-5] That in site 2 in the figure results in familial hyperproinsulinemia, an autosomal dominant defect with no apparent abnormality in carbohydrate metabolism, because the partially cleaved intermediate (B-C proinsulin cleaved at site 1 but not 2) has approximately 50% of the biological activity of insulin. A defect at site 1 also results in an autosomal dominantly inherited disorder of familial hyperproinsulinemia with carbohydrate intolerance of adult-onset diabetes, because the intermediate A-C proinsulin cleaved at site 2 but not at site 1 has less biological activity. Native proinsulin has less than 5%, whereas C-peptide has none, of the biological activity of insulin.[1,2] C-peptide's role appears to be the provision of the spatial arrangements required for the formation of the disulfide bonds.

Under normal circumstances, only a small quantity of proinsulin is released into the circulation, amounting to less than 15% of the total insulin measured by standard radioimmunoassay (RIA).[2] Small quantities of proinsulin intermediates also are released.[2] The greater proportion of proinsulin, however, is cleaved within the β cell into insulin and C-peptide.[1,2] Of most importance is the fact that during insulin secretion induced by various stimuli, one molecule of C-peptide is released with each molecule of insulin. Thus, the plasma of normal persons contains small amounts of proinsulin, proinsulin intermediates, and almost equimolar amounts of insulin and C-peptide. The metabolic half-life of C-peptide is longer than that of insulin; thus, the molar ratio of C-peptide to insulin in peripheral plasma is always greater than one, and the peak of C-peptide secretion or the nadir of its suppression appears to occur later than that of insulin.[6] How can these molecules be distinguished and what practical uses can be made from this distinction?[7]

The standard method now used for measuring insulin in biological fluid is by RIA. The principle underlying this method involves use of an antibody to a hormone and the competition between known and unknown quantity of this hormone to displace in a predictable manner a small amount of the radioactively labeled hormone from this specific antibody. It should be evident from the figure that an antibody to insulin will measure insulin and proinsulin, since the entire insulin molecule is still within its parent structure, but not C-peptide, which is clearly immunologically distinct. Separation of proinsulin from insulin, if desired for research purposes, can be achieved by various procedures such as chromatography to separate the larger proinsulin fraction prior to assay, the use of an enzyme that degrades insulin but not proinsulin, or the use of a C-peptide assay that will measure proinsulin but not insulin.[2] As is apparent from the figure, an antibody specific for C-peptide



Structure of human proinsulin. Arrows 1 and 2 indicate two sites of normal cleavage that yield insulin and C-peptide when arginine (ARG)-31 and -32 residues and ARG-65 and lysine (LYS)-64 residues are removed. During insulin secretion, equimolar amounts of insulin and C-peptide are released. Cleavage sites 1 and 2 are known mutation sites (see text) (from Gabbay[5]).

will measure C-peptide and proinsulin but not insulin. With the C-peptide assay, no interference should theoretically result from the antibodies to exogenous bovine-porcine insulin that develop in all diabetics after a period of insulin treatment.[2] These endogenous antibodies interfere with the RIA for insulin, and their presence confounds the interpretation of results in insulin-treated diabetics.[8] Thus, measurement of C-peptide will reflect β-cell secretory activity even in the presence of antibodies to insulin and will distinguish endogenous insulin secretion, which is accompanied by C-peptide from exogenous insulin administration; in the latter circumstance, there will be no measurable or inappropriately low C-peptide levels, even though RIA shows high insulin values in both circumstances.[8,9] These theoretical considerations form the basis of all practical applications of this assay.[10]

Elsewhere in this issue of the JOURNAL (p 1129), Rappaport et al demonstrate the application of C-peptide measurement to document the persistence of residual β-cell secretory activity in insulin-dependent diabetic children. Those children who could be maintained in good metabolic control as judged from urinary excretion of glucose and levels of glycosylated hemoglobin, despite low doses of exogenous insulin, had substantial residual β-cell function documented by C-peptide measurements. Those children with substantial C-peptide excretion had had their disease for less than one year. Beyond this period of recognized and treated disease, C-peptide excretion fell to negligible amounts, larger doses of insulin were required to maintain metabolic control, and more insulin-binding antibodies developed. Furthermore, residual β-cell function could be documented in many patients recovering from their initial episodes of ketoacidosis.

These findings are not surprising, nor are they really novel. Clinicians have long known that a large proportion of newly diagnosed diabetic children may enter a "honeymoon" period after treatment is first instituted.[8] During this period, the amount of insulin required to maintain apparently excellent metabolic control is remarkably little, and occasionally insulin may be temporarily discontinued. Reduction of insulin dose becomes necessary because of recurrent hypoglycemic episodes. This honeymoon phase lasts for a variable period but seldom longer than one year, and gradually increasing doses of insulin are subsequently required to maintain metabolic control. The use of a standard RIA for plasma insulin levels, performed early in the honeymoon phase after withdrawal of exogenous insulin and before antibodies to the injected insulin could confound the interpretation of results, has confirmed the clinical suspicion that residual insulin secretory activity must be present, at least early after diagnosis.[8,11] Consequently, in the period after initial diagnosis, C-peptide assays do not provide any more useful information in the management of the case than clinical response of the patient and the clinical acumen of the physician. Nevertheless, the C-peptide assay has proven to be an excellent research tool with which to document the extent and duration of residual β-cell function despite the develop-

ment of insulin antibodies.[7,8,10] However, precautions must be taken not to overestimate the magnitude of residual β-cell function. Antibodies to exogenous insulin will bind endogenous proinsulin and impair its degradation and metabolic clearance. Proinsulin will, as indicated above and as is evident from the figure, react in the C-peptide assay so that C-peptide levels may be spuriously high.[7] With appropriate methodologic precautions, however, careful studies using C-peptide have demonstrated that some residual β-cell function may persist for up to five years after diagnosis. These studies also demonstrated that "brittle" diabetes is almost always associated with near-total lack of insulinogenic reserve but that the reverse is not true; good control can be achieved by exogenous insulin despite absence of endogenous insulin reserve.[12] The article by Rappaport et al in this issue reaffirms and highlights all of these points. Most provocative of all is the claim by Danish workers that early diagnosis before the onset of severe ketosis, followed by intensive insulin treatment to normalize metabolism, increases the likelihood of preserving endogenous insulin production as reflected in C-peptide levels, which in turn facilitates diabetic control.[7,13] This "research" finding imposes some powerful obligations on the practicing physician. As a research tool, C-peptide has provided irrefutable evidence of residual β-cell function not only in diabetics but also of excessive insulin secretion in infants born to diabetic mothers.[14] In these infants, the maternal antibodies to administered insulin cross the placenta, producing interference in the measurement of the infant's serum insulin level by RIA.

It is not in diabetes but rather in the differential diagnosis of hypoglycemia that C-peptide measurement has its most practical application. In all forms of spontaneous hypoglycemia except insulinoma, endogenous insulin secretion, and therefore C-peptide secretion, decreases. When blood glucose concentration falls below 40 mg/dL, insulin secretion is curtailed, so that serum insulin concentration is low and usually less than 10 μU/mL. If, at the time of hypoglycemia, serum insulin concentration is inappropriately high, determination of C-peptide levels permits differentiation between an insulinoma and factitious hyperinsulinemia as a result of self-administered insulin.[15] In the former, C-peptide levels are high and at least equimolar to insulin levels, reflecting endogenous secretion, whereas in the latter, C-peptide levels will be low or absent, reflecting curtailment of endogenous insulin secretion by the exogenous insulin. When factitious hypoglycemia is suspected, including this possibility as a manifestation of child abuse, the triad of low plasma glucose, high immunoreactive insulin, and suppressed C-peptide levels is pathognomonic of exogenous insulin administration. And, in cases of suspected insulinoma where spontaneous hypoglycemia may occur only intermittently, it is no longer necessary to employ provocative maneuvers such as prolonged starvation to provoke hypoglycemia and to simultaneously measure insulin levels; the problem of having a physician or nurse on hand precisely when the hypoglycemic episode occurs is well known to those who have used this procedure. With the availability of C-peptide measurement, it is possible to rapidly exclude insulinoma as the cause of the hypoglycemia by means of an intravenous bolus (0.1 unit/kg) or infusion (0.1 unit/kg for one hour) of insulin. C-peptide levels will fall as hypoglycemia develops from the injected insulin but will not appropriately fall in patients with insulin-secreting tumors.[9,16] Indeed, the standard, two-hour, arginine-insulin tolerance test used by endocrinologists to evaluate pituitary function will provide information on all forms of hormone deficiency (growth hormone, cortisol, glucagon) or hormone excess (endogenous insulin-C-peptide) that might be responsible for the hypoglycemia.[17] If all results are normal, a nonhormonal cause of hypoglycemia is implicated. Obviously, these tests should be performed under strict medical supervision by physicians familiar with the procedure, with glucose readily available.

It has been over 50 years since the discovery of insulin, but only in the past 15 years have studies elucidated some details of its structure, biosynthesis, and function. Complete understanding of insulin's mechanism of action is still lacking; however, insulin continues to be the model for understanding hormone synthesis and its disorders. This understanding provides new insight into the causes of diabetes and practical application to diagnose various disorders of carbohydrate metabolism. The applications of C-peptide, of which the report by Rappaport et al is but one example, reflect the harmonious interplay between basic scientific research and its clinical applications.

New Evidence on Food Additives and Hyperkinesis

A Critical Analysis

The Feingold diet continues to be a matter of controversy. In this MARGINAL COMMENT, *Dr Esther Wender discusses the findings of two studies recently reported in* Science. *Rebuttals by the authors of these two studies follow in sequence.*—ED.

Just at a time when Feingold-diet watchers in the scientific community have concluded that his food-additive-free diet is of little or no proven value in the treatment of hyperactivity and learning disability (unpublished data presented at the Conference on Nutrition and Behavior, Franklin Institute of Philadelphia, Williamsburg, Va, March 10-12, 1980),[1] two articles published in a recent issue of *Science*[2,3] have stimulated further comment that this dietary treatment is effective (*New York Times*, April 1, 1980, p C1; *Science News*, March 29, 1980, pp 199, 204). The April 9 edition of *Pediatric Notes*,[4] for example, reports briefly on these two articles and then concludes, "The Feingold diet is in with a bang. It doesn't matter how you view these studies, it seems quite clear that food dyes will have to go." It most certainly does matter how one views these studies, and this is why a brief review of both reports is the topic of this MARGINAL COMMENT.

The first investigation was by Weiss et al,[3] who studied 22 preschool-aged children recruited through advertisements requesting volunteers who had already been treated with the food-additive-free diet and had responded favorably. Both the treatment and the report of favorable response had been based on uncontrolled, informal clinical trials. These children were not selected to meet criteria for the diagnosis of either learning disability or the hyperactivity syndrome. All of them displayed behaviors that were troublesome to their parents, but no diagnostic evaluation was attempted. The patient population, therefore, was not necessarily either hyperactive or learning disabled and the group was highly selected on the basis of previously reported improvement on the food-additive-free diet.

These 22 children were then placed on a strict Feingold diet, which excluded the preservatives butylated hydroxytoluene (BHT) and butylated hydroxyanisole (BHA) as well as the usual exclusion of foods containing artificial colors and flavors and foods said to contain natural salicylates. (The children had already been on less strictly managed food-additive-free diets.)

They were then challenged daily for eight consecutive weeks with either a mixture of artificial food colorings or a placebo that contained no artificial colorings and was indistinguishable from the active challenge. The food-coloring challenge was given once each week on randomly assigned days. The mixture contained 35 mg of food coloring, which was considered to be the average amount consumed in an *entire day* by young children. Behavior was observed primarily by the parents, who listed target symptoms at the beginning of the study and rated these targeted behaviors on each challenge day. When teachers were available, they also rated target symptoms. Outside observers periodically made home visits to check on the accuracy of parent reports, but for each family this occurred infrequently. As long as the challenges are truly indistinguishable from each other, subjective parent ratings should not consistently favor one kind of challenge over the other.

In only one child did most of the target behaviors seem worse at the time of the active challenge as compared with the placebo challenge. Because that child was very young (2 years 10 months), school observations were not available. In one other child, the authors reported equivocal changes of doubtful clinical substance. Without independent corroboration, the results in this one child cannot be accepted as good evidence of a relationship between food colorings and behavior for two reasons: first, in two other studies,[5,6] there were similar reports of behavioral change by a parent, but in both of these studies, other observations were available and did not confirm the parents' report; second, independent corroboration is necessary to ensure that the parents' report is not based on their ability to distinguish between the active and the placebo challenge, a distinct possibility since the presence of artificial colorings can be detected by a technique known as "kitchen chromatography." This refers to a separation of colors that can be seen when the food that contains the mixture of artificial colorings is mixed with water and allowed to soak into an absorbent napkin or towel.

The authors state that the aim of their study was "simply to determine if behavioral sensitivity to color additives could be demonstrated in a controlled trial" and not to estimate prevalence. Yet Dr Weiss is reported to say, in response to questions about this study, that "Even if only one percent of children are affected, that's still a lot of children" (*New York Times*, April 1, 1980, p C1). What he fails to mention is that these 22 children represent a very highly selected group who were already considered to have improved with dietary treatment, and that 21 of them, previously identified as Feingold-diet responders who deteriorated consistently with dietary infractions, failed to demonstrate that pattern when the dietary challenge was administered in a placebo-controlled fashion.

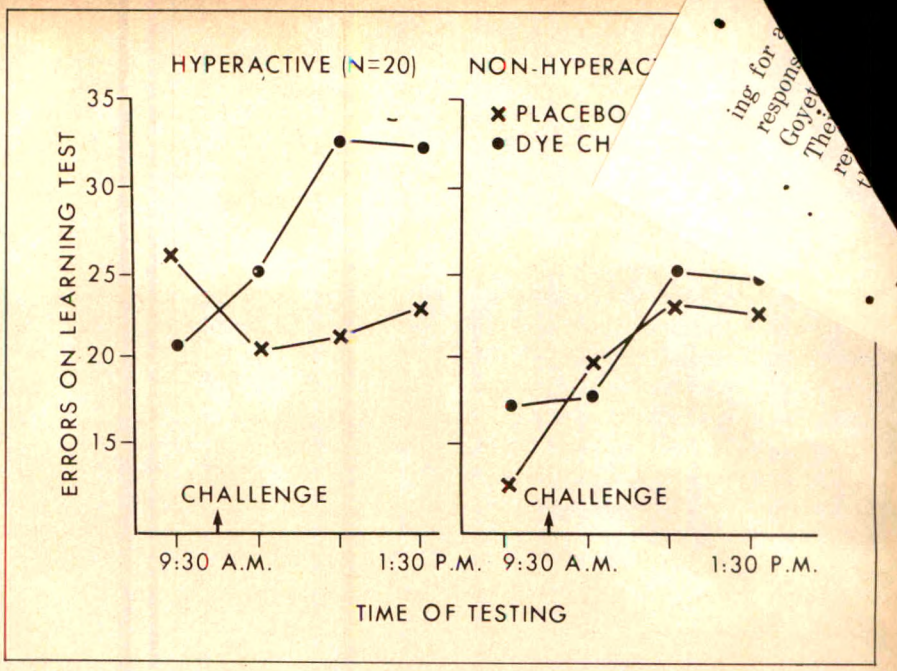
The second study is reported by Swanson and Kinsbourne and stems from research conducted at the Research Institute at the Toronto Hospital for Sick Children.[2] These investigators did not directly evaluate the hypothesis generated by Dr Feingold. For example, this was not a study of the effects of food additives on behavior even though Dr Feingold claims that his diet produces behavioral change. Instead, they studied the effects of food colorings on a laboratory task that measures the ability to sustain attention. Swanson and Kinsbourne measured behavioral change in

this and earlier studies but found no differences between the active and placebo challenges.

In this study, children were placed on the Feingold diet and were then challenged with a mixture of artificial food colorings in doses of 100 and 150 mg, given as a bolus in an opaque capsule. The authors state that the larger dose is at the 90% level for the amount of food coloring ingested by children in an *entire day* according to the food-coloring intake survey made in preparation for the study of Weiss et al.[3] This amount is far in excess of the dose likely to be ingested with the dietary infractions described by Feingold and others.

The study population consisted of two groups of school-aged children whom Swanson and Kinsbourne call "hyperactive" and "nonhyperactive" based on their response to stimulant medication. They measured medication response by the child's performance following the administration of a single dose of medication on a laboratory task that measures the ability to sustain attention. Once they divided their patients into favorable and adverse medication responders, they summarized the scores on the ten questions of the Conners Teacher Questionnaires that correlate most highly with a diagnosis of hyperactivity and found that the favorable responders yielded an average score of 16 and the adverse responders yielded a mean score of 12.6. On these ten questions, a score between 0 and 9 is within normal range and a score of 15 is 2 SDs above the mean. The 12.6 mean score of the adverse responders is therefore definitely higher than average but does not reach 2 SDs above the mean.

The designations hyperactive and nonhyperactive based on these criteria are very misleading. Diagnosis of the behavioral syndrome often called hyperactivity is based primarily on a history of at least two years' duration both at school and at home of excessive activity and restlessness, impulsiveness, and inattention and distractibility.[7] Though the Conners questionnaire ten-item score often correlates with hyperactivity as indicated by history, the questionnaire cannot replace the history as a diagnostic tool. Also, a favorable response to



Responses of hyperactive children and nonhyperactive children challenged with food-dye blend or with placebo (from Swanson and Kinsbourne[2]).

medication does not establish, and an adverse response does not preclude, the diagnosis. The group that these authors call nonhyperactive might better be described as "less hyperactive."

Swanson and Kinsbourne demonstrated a statistically significant increase in the number of errors made 1½ and 3½ hours after the food-coloring challenge compared with the placebo challenge, but only in the hyperactive group. If one looks, however, at their data, there appears to be a striking difference in the placebo performance between the two groups (Figure). In the nonhyperactive group, the error rate at baseline was low and gradually rose with repeated testing. This pattern would be expected since children fatigue with frequent testing. By contrast, in the so-called hyperactive group, the error rate at baseline was at its highest and then dropped following the placebo challenge. The reason for those different patterns of placebo response in the two groups is not apparent. Swanson et al, in other articles using the same laboratory task, obtained placebo-response patterns like that seen in the nonhyperactive children.[8] The *pattern* of response seen after both the active challenge and the placebo challenge in the nonhyperactive group was very similar to the pattern seen after the active challenge in the hyperactive children but at a higher rate in this latter population, as would be expected since they were more symptomatic. Because of the unusual placebo-response pattern in the so-called hyperactive group, this study needs to be replicated before the results can be accepted.

It is unfortunate that these two articles are being cited as supporting the claim that artificial food colorings play a substantive role in producing symptoms of hyperactivity. The study of Weiss et al[3] actually provides some of the most convincing evidence that food colorings have nothing to do with the improvement in behavior seen by parents when their children are placed on the Feingold diet. All 22 of the children in this study were, according to their parents, dramatic diet responders who deteriorated with dietary infractions. Yet when they were fed, under double-blind conditions, large doses of food coloring (much more than would be consumed in any ordinary diet infraction), no such deterioration was seen, except in one child where the change in behavior was noted only by the mother.

In the Swanson and Kinsbourne study,[2] no *behavioral* change was noted even with food colorings given at doses of 100 and 150 mg. They therefore turned to a laboratory task, look-

short-lived pharmacological e that had been described by te et al in an earlier report.[9] r' method of testing involved peated tests over short periods. In his situation, both practice and fatigue . effects must be taken into account. Since they found differences between the active and placebo challenges only in the more symptomatic group and since those differences are associated with an unexpected pattern of placebo response seen in that group, their results must be replicated before they can be accepted. Conners et al attempted to replicate Swanson's findings but found no consistent differences between the placebo and the food-coloring challenge.[10] In summary, the Swanson and Kinsbourne study showed none of the behavioral changes that Dr Feingold stresses, and the findings on the laboratory learning task cannot be accepted until the unexpected placebo response is explained.

In Rebuttal

In her discussion of a recent article by us[1] on the effect of food dyes on hyperactive children, Dr Wender raises an interesting point about the performance of our subjects during the day following challenges with placebo. She claims that the differences in performance between the dye and placebo conditions can be accounted for by an "unexpected pattern of response" by the hyperactive group of subjects in the placebo condition, and she recommends that our results be seriously questioned until this unexpected response is explained. In fact, for the procedures used in our study and data analysis, the pattern of performance in the hyperactive group after a placebo challenge is virtually identical to the pattern we reported earlier,[2] and it is the pattern of the nonhyperactive (or less hyperactive) group that differs from our previous report. Thus, the *opposite* of Dr Wender's claim may be true for our data.

What does this mean with respect to her comment on our findings? Following her logic, we should accept the presence of a dye-induced effect in the hyperactive group since we have explained the pattern of response in the placebo condition, which she challenged, but we should *not* accept the lack of a dye-induced effect in the nonhyperactive group since they were the ones who manifested an unexpected pattern of response in the placebo condition. Of course, we do not believe that this is reasonable, nor do we believe that Dr Wender would draw this conclusion. Thus, we present the following discussion to address the question she has posed.

Dr Wender's confusion about the expected and unexpected pattern of performance after a placebo administration is understandable, since a subtle methodological difference in how the data are analyzed determines the expected pattern. We have discussed this in detail elsewhere.[2] When the data from individual subjects in the placebo condition are taken directly without an adjustment for baseline, as was done in our article,[1] then in the group averages a pattern reflecting an initial improvement from the first to the second test, followed by a gradual deterioration across subsequent tests, is to be expected (see Kinsbourne et al,[2] Fig 4). However, when the initial score of the day is used to adjust the subsequent scores of each subject to reflect percentage change from baseline,[3] then only a pattern of gradual deterioration appears in the group averages representing performance after an administration of placebo (see Kinsbourne et al,[2] Table 1). The different appearance of the group curves for these two procedures is due to the differential weighting of scores for extreme subjects by these methods when the data from individual subjects are combined.[2]

What pattern would emerge if we did adjust for baseline? If we were to use an average baseline score across the two challenge days and adjust for baseline according to procedures we have used before,[3] than the effect of the food-dye challenge would be magnified in the hyperactive group since the initial score in the placebo condition is higher than the initial score in the food-dye condition (see Swanson and Kinsbourne,[1] Fig 1a).

Despite the difficulty in establishing the expected pattern of performance after placebo administration in our study on food dyes, the implication of Dr Wender's point is valid: the two groups (the hyperactive and nonhyperactive in our terminology, or the more hyperactive and the less hyperactive in her terminology) do seem to differ in the pattern of performance following placebo administration. We have performed an alternative decomposition of the three-way interaction reported in our

article (involving patient type, challenge, and test time) to verify this difference. Instead of performing a simple effects analysis of the within-subject factor (challenge and test time), which is the preferred procedure and the one reported in our article,[1] we analyzed the effects of one between-subject factor (patient type) and one within-subject factor (test time) for the placebo condition and the food-dye condition separately.

In this simple effects analysis of the placebo data, the interaction of the two factors (patient type and test time) was significant ($F(3,108) = 5.45$, $P < .01$), confirming Dr Wender's point that the pattern of performance for the two groups did differ in the placebo condition. A further decomposition of this significant two-way interaction revealed that the two groups differed *only on the first test*, which was given before the challenge was administered, and that no group differences occurred for the three tests given after the challenge. We have no explanation as to why the two groups differed on the first test within the placebo condition, but we should point out that the variation across the two challenge days for performance on the first test was not significant for either the hyperactive or the nonhyperactive group. The average performance for the subjects in the hyperactive group was worse in the placebo condition than in the food-dye condition, but the difference (−5.9 errors) failed to reach statistical significance (see Swanson and Kinsbourne,[1] Table 1). The average performance for the nonhyperactive subject was better in the placebo condition than in the food-dye condition, but again the difference (+4.2 errors) was not statistically significant.

When the data from the food-dye condition and the placebo condition are analyzed separately, the effect of the type of challenge (dye or placebo) cannot be evaluated directly in the simple effects analysis of the factors of patient type and test time for the data from these two conditions treated separately. Of course, this is why we chose to perform the other decomposition of the three-way interaction in our original article.

If the problematic data from the first test are not considered, the significant effect of the food-dye challenge on the later tests remains. Or, if a nonparametric analysis is used (as we reported in Table 1 of our article[1]), the statistically significant effect of the challenge with food dye remains. Furthermore, we stand behind our procedure for decomposing the significant three-way interaction in our original report. We believe that Dr Wender's opinion qualifies as a post-hoc comparison of a set of data in which a variety of tests or comparisons can be made. However, if the established procedures of analysis of variance are followed (which are designed to prevent the investigator from focusing on spurious or chance differences), then the question posed by Dr Wender would be unlikely to receive serious consideration. Even if it is considered, our conclusions remain unchanged.

Another problem in Dr Wender's comments on our article concerns her reference to Conners' use of our learning test in a study of the effects of food dyes on hyperactive children.[4] He used challenges of 26 mg of food dye and found no significant differences between dye and placebo challenges. This replicates our earlier finding for 26-mg challenges[5]; only when we went to much larger challenges (100 mg and 150 mg) did we find significant effects.[1] Conners[4] describes his data as being suggestive of an acute effect of food dye and he states with "20-20 hindsight" that he should have increased the amount of dye in the challenges to maximize the chance of eliciting a response. This is the main point of our article in *Science*, which our last sentence reinforces: "When a blend of dyes is used, a high dose may be necessary to elicit a behavioral response in hyperactive children."[1] We see no reason for our results to be seriously questioned on the basis of Conners' study, as suggested by Dr Wender, since his results are consistent with our earlier findings.[5]

Dr Wender has an important point to make in her marginal comment, and the readers of the JOURNAL deserve to have it clearly stated to prevent misunderstanding. The results of the two articles in *Science*[1,6] do not confirm all (or even most) of the claims made for the Feingold diet. They were not designed for that purpose. In fact, two of the findings (that only two of 20 children showed any response to food-dye challenges in the study of Weiss et al[6] and that no behavioral response was documented by rating scales in our study[1]) can be used to argue against the hypothesis that a large dose of food dye will dramatically affect in the short term the behavior of hyperactive children. On the other hand, the statistically significant effects of food dyes reported by Weiss et al[6] and by us[1] cannot be discounted, and they do provide some limited support for the aspects of the Feingold hypothesis that they were designed to test. To put the positive and negative aspects of these two studies into perspective, it is not necessary to attempt to discredit the statistics or the data from these studies in order to ignore their positive aspects. It is effective and accurate to point out the narrow focus and negative aspects of these studies, and then to interpret the positive results in that context.

UNIVERSITY OF CALIFORNIA MEDICAL CENTER LIBRARY

In Rebuttal

David P. Rall, Director of the National Institute of Environmental Health Sciences and of the National Toxicology Program, once challenged an audience with the following question: Suppose that thalidomide, rather than inducing structural deformities, had instead depressed IQ scores by 10%; would we ever have suspected it of adverse effects?

The answer to that question is disquietingly obvious. Rall framed it to illustrate the problems now taunting the science of environmental toxicology. Absence of death and frank disease are too blunt to serve alone as evidence of safety. The community demands protection against the subtle, insidious, often delayed consequences of exposure to toxic environmental agents, consequences exemplified by behavioral disturbances. Behavioral toxicology is a discipline created by that concern. Although a young discipline—the first meeting was organized in 1972[1]—it is exerting a widening influence. In the Toxic Substances Control Act of 1976, which mandates premarket toxicity evaluation of all new chemicals introduced into commerce, Congress specified behavior as one of the salient criteria. Japan and Great Britain now require behavioral toxicity evaluations of new drugs. And the current anxieties stirred by obstetric medications and alcohol consumption during pregnancy center on their enduring behavioral consequences.

The study that my collaborators and I conducted[2] grew out of that perspective. Our aim was not to estimate prevalence of sensitivity to food colorings but simply to determine if behavioral measures could detect doses normally consumed by children. We did not test the Feingold diet as therapy. We did our study because the issue of behavioral toxicity from food additives far transcends in societal importance the role of Feingold's elimination diet as therapy.

To review the study, 15 male and seven female children, 3 to 7 years old, composed the sample. None suffered from notable medical or psychiatric problems. Almost all subjects were solicited through the Kaiser-Permanente system (not by advertisements). All had been eating an elimination diet for at least three months before entering the study and, according to parents, had shown improvement in problem behaviors on the diet. The experiment lasted 11 weeks. On every day of that period, the child consumed a specially formulated bottle of soft drink. The first three weeks and last week constituted baseline periods. On eight randomly determined days during weeks 3 through 10, the drink contained a blend of seven certified food colors instead of the control preparation. On every day of the study, the parent participant recorded counts and ratings of ten individualized target behaviors, completed the Conners ten-item Parent-Teacher Questionnaire, and performed several other associated duties.

We had to labor under several limitations. First, we administered a dosage, 35.6 mg/day, that we calculated from a survey as the mean daily intake of children between 1 and 6 years old who were enrolled in the Kaiser-Permanente system. Restrictions imposed by human-subject review committees precluded tests of higher doses. Furthermore, we administered this dose only once weekly, on the average. Yet some children may consume as much as 184 mg daily, the Food and Drug Administration estimate of mean daily consumption is 75 mg, and other experiments[3] suggest a dose-response relationship. Second, it would have been statistically advantageous to challenge on more than eight occasions,[4] but 11 weeks is a long period for parents whose lives are constrained by a demanding protocol. Third, trained observers, whose reliability could be quantified, might have given us more sensitive indices of response, but their cost could have easily doubled our budget. Our observers visited once weekly (not "infrequently"). These limitations curtailed the sensitivity of the experiment. Despite them, we detected two responders. One, a 3-year-old boy, showed significant enhancements of the two target behaviors claimed by his mother as those most pronounced after previous dietary infractions. The other, a 34-month-old girl, showed significant elevations on five of the seven aversive target behaviors, on the Conners Questionnaire, and on other indices.

Dr Wender contends that these results were either due to the ability of parents to detect the dye blend or else may represent a statistical artifact. Her insinuations about "kitchen chromatography," however, are invalid. As we noted, the control and challenge drinks were "indistinguishable by sight, smell, taste, or *stain color*." We were aware of that problem; we solved it, as reported, by preparing a freeze-dried monoblend of the seven colors (which yielded a more uniform stain) and, because our blend left a pink stain, by adding varying concentrations of cranberry coloring to both drinks to foster maximum confusion. I am astonished by Dr Wender's assertion because she had access to our FDA report, which described these precautions in detail. I also described this procedure and its development at a small meeting in January 1979 that Dr Wender cochaired. Perhaps she was confused by my narration of our attempts to deter kitchen chromatography. The data also contradict her hypothesis. Not all indices responded equally to challenge, as our figures demonstrated. Not all indices, moreover, responded equally on any particular challenge day. Any knowledgeable experimenter would expect far more uniformity had the code been breached.

Dr Wender's second objection is quasistatistical, that is, one mild and one cogent case in 22 children cannot be adduced as evidence of behavioral sensitivity to food dyes. This objection betrays an unfamiliarity with both statistics and toxicology. Dr Wender seems unaware of certain critical statistical implications of the Feingold hypothesis. Nowhere does Feingold claim that all children respond favorably to the diet or adversely to food dyes. A population, however, composed of both susceptible and resistant persons reduces the chances of

finding a statistically significant response of the group to treatment and violates the assumptions underlying conventional statistical models. Assume, for example, a sample population containing 30% responders. If a treatment shifts the mean of the responders by 1 SD, it would take samples of 265 subjects from that population to attain consistent statistical significance. Such problems are now being addressed by statisticians in contexts ranging from responsiveness to antibiotic treatment[5] to the impact of air pollution on asthmatics[6] to the Feingold hypothesis. A human population is not a jar of jelly beans.

Dr Wender makes other misleading allegations. For example, her first sentence asserts that "Feingold diet watchers" had concluded that his diet was of little value. Which watchers? Her first reference, to a workshop on nutrition and behavior, perplexes me because I was one of the organizers of that meeting and chaired the section on toxicology. She was not present. Her second reference is a document sponsored by the Nutrition Foundation, but she is one of its authors, and a consultant to the Foundation. It is also incorrect that we attempted no diagnostic evaluation of the children. They were thoroughly examined by Kaiser-Permanente pediatricians and, if necessary, by psychiatrists and psychologists (as we have reported). Dr Wender also tends to equalize our challenge study with the total Feingold diet. Coloring elimination is only one component of that diet. And, to stress again, we challenged only intermittently with the mean daily dose. Our study design would not detect cumulative effects.

Dr Wender's position also reflects an uncritical appraisal of the literature. Two controlled trials of the total diet have demonstrated statistically significant improvements in treated children. One reported an incidence of 50% (23/46).[7] Another observed improvement in four or five of 15 subjects.[8] A coloring challenge study detected adverse consequences in about 25% of a sample of 24 children.[9] Dr Wender's interpretation of the study of Swanson and Kinsbourne[3] also reflects confusion. After denying any action of food dyes or the elimination diet on "learning disabilities," she dismisses as irrelevant an experiment that demonstrated learning deficits after dye ingestion. She doesn't grasp the fact that learning is an aspect of behavior. She describes the task used by Swanson and Kinsbourne[3] as merely a test of attention without, apparently, realizing that now hyperkinesis is considered an attention deficit disorder.

The most dismaying feature of Dr Wender's critique, however, is her insensitivity to the toxicological issues. Food additives are not now tested for behavioral toxicity.[10] Safety is gauged mainly by absence of detectable pathologic conditions.[11] From feeding studies in rodents, toxicologists typically calculate a "no-effect level," then divide by a 100-fold safety factor to determine an allowable daily intake, the amount that presumably can be ingested without harm.[12] My statement about the importance of a 1% incidence was made in that context. Even that incidence denotes a zero safety factor, because the allowable daily intakes for food dyes greatly exceed the quantities evoking behavioral effects. Dr Wender's statements about the "excess" quantities ingested within a limited time are also misdirected. Without more knowledge of food-dye pharmacokinetics and amounts in food, we do not know if it is an important issue. Thirty grams of ice cream or 100 g of a carbonated beverage may contain as much as 10 mg of tartrazine.[13]

Safety factors are especially critical for the developing organism. As readers of the JOURNAL are distinctly aware, the immature nervous system is more sensitive to many toxic agents than is the adult nervous system, sometimes exquisitely so. Methylmercury is only one compelling example.[14] The Feingold literature offers a disturbing parallel. All ten of a group of preschool-age hyperactive boys responded positively to an elimination diet.[7] The youngest subjects in an early color challenge study proved to be the most sensitive.[15] The two detected responders in our experiment were also among the youngest. Neonatal rats display behavioral abnormalities when given a blend of food colors at a dose approximating ours.[16]

Behavioral teratology designates that branch of behavioral toxicology whose focus is the functional aftermath of perinatal toxic exposure. Given the enhanced sensitivity of the fetus and neonate to so many other agents, should not prudent clinicians caution pregnant and nursing women and parents of young children about the conspicuous absence of behavioral data in food-additive safety testing, as well as the balance of risks and benefits? Food dyes are cosmetic additives and serve no crucial nutritional function. Growing restrictions on food dyes by other governments,[13] coupled with the expanding role of behavioral assessment in toxicology, indicate that Dr Wender's complacency is far from universal.

Is There an Optimal Time to Schedule Residency Interviews?

The process of applying for a primary care residency position has become increasingly complicated in recent years. Some senior medical students seem to spend an inordinate amount of time and energy on this effort that may begin at the end of their junior year and extend up until the deadline for the National Resident Matching Program (NRMP) during the first week of January. The prospective applicant generally schedules interviews with five to ten programs that often vary in size, geographic location, and university or community affiliation. Larger residency programs may set up predetermined interview days, whereas smaller programs tend to schedule interviews at the convenience of the applicant.

Does it matter when the prospective applicants schedule their interviews? Applicants say that they are told, usually by faculty advisors or fellow students, that interviews should not be scheduled too early in the course of the academic year for fear that they will have been forgotten by the time the rank order of applicants is transmitted to NRMP. Other students are advised not to come too late for fear that program directors might believe that they have not demonstrated sufficient interest in their particular program.

We studied whether the date of the applicant's interview for a residency position affected his or her rank order for the NRMP.

MATERIALS AND METHODS

All applications (excluding those from our own students) to the Pediatric Residency Program of the Upstate Medical Center, Syracuse, NY, for the five-year period of 1974 to 1978 were reviewed. In each year, applicants were divided into four groups by their numerical NRMP ranking: group 1, top 20; group 2, 21 to 40; group 3, 41 to 60; and group 4, 61 or greater. The dates of the applicant interviews were recorded by months: July-August, September, October, November, and December.

Ranking of Residency Applicants by Month of Interview

	Ranking Group*				
Applicant Interview	**1**	**2**	**3**	**4**	**Total†**
July-August	6	11	6	4	**27**
September	8	8	11	12	**39**
October	16	28	32	28	**104**
November	28	26	31	32	**117**
December	15	14	9	21	**59**
Total	**73**	**87**	**89**	**97**	**346**

*Ranking group indicates numerical National Resident Matching Program ranking: group 1, top 20; group 2, 21 to 40; group 3, 41 to 60; and group 4, 61 or greater.
†Applicants from Upstate Medical Center, Syracuse, NY, excluded.

COMMENT

The data from the applicant record review are given in the Table. Each cell of the Table represents the number of applicants in the four ranking groups by month of interview during this five-year period. No trend in ranking by month of interview is noted by perusal of the Table. A χ^2 test for $r \times c$ tables was 12.95 with 12 *df*, giving a probability of approximately .4. There were no significant differences in the ranking categories by the month of interview, which demonstrates that the timing of the interview was neither an advantage nor a disadvantage in the applicant's ultimate ranking.

Despite this finding, we have noted a striking change in the time that applicants come for interview. In 1974, 13 students visited our program in the summer months, while in 1978 only one student was interviewed during that period. Similarly, there has been a drop in applicants seen in December, from 14 in 1974 and 21 in 1975, to four in 1978. October and November have been the peak months of visitation for four of the past five years. Scheduling all applicants during this limited time period has become more difficult.

The timing of the program interview for residency, at least in the pediatric department at the Upstate Medical Center, does not affect subsequent ranking for the NRMP. Interviews should be scheduled at the convenience of both the applicant and the program.

Urine C-peptide, β-Cell Function, and Insulin Requirement

Elizabeth B. Rappaport, MD; Robert A. Ulstrom, MD; Donnell D. Etzwiler, MD; Daniel Fife, MD; Bo E. Hedlund, PhD; Michael W. Steffes, MD, PhD

• Urinary C-peptide excretion was investigated as a method for monitoring β-cell function in diabetic patients and for studying the contribution of endogenous insulin production to diabetic control. Control subjects had variations in serum and urine C-peptide immunoreactivity that correlated with basal and meal-related insulin secretion. In a group of well-controlled juvenile diabetic patients, those receiving high doses of insulin had low or negligible C-peptide excretion, whereas most patients with low exogenous insulin requirements had near-normal urinary C-peptide excretion. Patients treated for diabetic ketoacidosis had recovery of β-cell function as measured by C-peptide immunoreactivity in serial urine specimens. Thus, measurement of urinary C-peptide excretion is a simple technique that may be useful in assessing endogenous insulin production in juvenile diabetic patients.

(*Am J Dis Child* 134:1129-1133, 1980)

From the Departments of Pediatrics (Drs Rappaport, Ulstrom, and Fife) and Laboratory Medicine and Pathology (Drs Hedlund and Steffes), University of Minnesota School of Medicine, Minneapolis; and the Department of Pediatrics, St Louis Park Medical Center, St Louis Park, Minn (Dr Etzwiler). Dr Rappaport is now with the Charles A. Dana Research Institute and the Harvard-Thorndike Laboratory of Beth Israel Hospital, Department of Medicine, Beth Israel Hospital and Harvard Medical School, Boston.

Reprints not available.

Development of an assay for C-peptide in serum and urine has allowed investigation of endogenous insulin production in persons with diabetes mellitus who are receiving exogenous insulin. In 1973, Block et al[1] determined, by measuring serum C-peptide immunoreactivity, that the remission period characterized by improved carbohydrate tolerance and diminished insulin requirement in some juvenile diabetics was the result of renewed β-cell activity. Other workers have confirmed, by measuring both fasting and stimulated serum C-peptide concentrations, that patients with juvenile diabetes have significant endogenous insulin production.[2-7] These data were gathered using serum samples and could be obtained only in a hospital or clinic. They provided information on C-peptide secretion during a limited period.

Measurement of C-peptide immunoreactivity in the urine has been proposed as a method for obtaining integrated data on β-cell function in diabetic patients.[8,9] We undertook to establish the validity of urine C-peptide measurement as an index of β-cell function by simultaneous assessment of serum insulin and C-peptide and urine C-peptide levels in a group of normal adults. We made similar measurements in three children with juvenile-onset diabetes during a three-hour oral glucose tolerance test.

For editorial comment see p 1119.

In nine patients with juvenile-onset diabetes, we measured 24-hour urine C-peptide excretion. These data were correlated with daily insulin dose, duration of clinical diabetes, and qualitative assessment of insulin-binding antibody concentrations in serum. We also measured urine C-peptide excretion in three patients during episodes of diabetic ketoacidosis.

SUBJECTS

These investigations were approved of by the University of Minnesota (Minneapolis) Committee on the Use of Human Subjects in Research. Informed consent was obtained from control subjects and from patients and/or their parents.

Control Subjects

Six healthy subjects, three men and three women ranging in age from 19 to 33 years and each being within 10% of ideal body weight, participated in the study. There was no history of diabetes mellitus in first-degree relatives of any of these subjects.

Following a dietician's instructions, sub-

jects consumed diets containing at least 200 g of carbohydrate daily for three days prior to hospitalization. Subjects were admitted to the Clinical Research Center the day before the 24-hour test period, during which time they received three equicaloric meals at 7:30 AM, 12:30 PM, and 5:30 PM. Total calories were appropriate for height, weight, and age. Fluid intake during the test period was 2 to 3 L. Only water was allowed between meals. Subjects were permitted free activity on the ward.

Blood samples for glucose, C-peptide, and insulin concentrations were obtained via an indwelling needle at half-hour intervals beginning a half hour before breakfast and continuing for 24 hours. Serum was separated and frozen (−20 °C) in aliquots for later assay. Urine was collected in timed fractions (two to five hours' duration) throughout the day and overnight.

Ten healthy children of hospital personnel served as control subjects for total 24-hour urine C-peptide excretion. Their ages ranged from 3 to 14 years. Their urine was collected at home. No effort was made to regulate diet or physical activity during these collections.

Juvenile Diabetic Patients

Three children (aged 4, 5, and 14 years) were discovered to be diabetic because of polyuria and polydypsia without ketoacidosis. Prior to initiation of insulin therapy, all three underwent three-hour oral glucose tolerance tests with simultaneous measurement of serum insulin and C-peptide and urinary C-peptide excretion.

In three patients (aged 15, 16, and 23 years), urinary C-peptide excretion was studied during episodes of ketoacidosis. The condition of two of the three was newly diagnosed, and that of one had been diagnosed eight months prior to the time during which he was studied.

In nine juvenile-onset diabetic patients who were 4 to 20 years old, 24-hour urinary C-peptide excretion was measured. They had clinical diabetes of two months' to 7½ years' duration. Their insulin doses were 11 to 47 units/sq m/24 hr (0.3 to 1.5 units/kg/24 hr) (Table 1). These insulin doses were determined by the patients' primary physicians and were not adjusted for the purposes of this study. Eight of the nine followed their normal daily living patterns during the time of study. One was hospitalized for investigation of his low insulin requirement. Subjects selected were known to be in good diabetic control. Each was studied only if the total 24-hour urine glucose excretion on the day of study was less than or equal to 5% of the daily carbohydrate intake. The adequacy of these selection criteria was substantiated by measurement of glycosylated hemoglobin concentrations in seven of the nine patients. At the end of the 24-hour collection period, blood was drawn for measurement of serum creatinine and glycosylated hemoglobin levels (except in patients 6 and 8).

METHODS

C-peptide immunoreactivity in urine and serum was measured using a double-antibody radioimmunoassay (RIA) kit (Calbiochem) for human C-peptide that uses rabbit antiserum prepared against synthetic human C-peptide, iodine I 125-tyrosylated synthetic human C-peptide, and synthetic C-peptide standard. Goat antirabbit γ-globulin is the precipitating antibody. Urine samples were diluted as necessary with the assay buffer, 1% bovine serum albumin in 0.01M phosphosaline with 0.05M ethylenediaminetetraacetic acid (EDTA), having a pH of 7.6, and 0.01% thimerosal. The sample volume was 200 μL, and the total volume in each assay tube, 900 μL. The lower limit of sensitivity of the assay was 0.5 ng/mL ($P < .01$). Dilution of the urine with buffer did not alter the measured urine C-peptide content.

Urine samples were collected in glass or plastic containers and kept refrigerated during the collection period. Sodium hydroxide (1N) was added to samples to adjust the pH to 7 to 8. Samples were centrifuged to remove sediment, and aliquots were kept frozen until analyzed.[8] Urine and serum creatinine levels were measured by the alkaline picrate method.[10]

Glycosylated hemoglobin concentration was measured by a technique similar to that of Trivelli et al.[11] Whole blood (collected with heparin or EDTA as an anticoagulant) was centrifuged. From 50 to 100 μL of packed blood cells was transferred to a 1.5-mL centrifuge tube and mixed with an equal volume of lysing solution (0.1M potassium cyanide containing 1% octoxynol-9 [Triton X-100]); 1.2 mL of buffer 1 (33 mM sodium biphosphate, 8.3 mM sodium phosphate, 10 mM potassium cyanide) was added and the tube was mixed again. The tube was then centrifuged in a microcentrifuge (Eppendorf). The clear supernatant fluid was added to a column containing a cation exchange resin (Biorex-70) (70 × 100 mm) and the glycosylated hemoglobins were eluted with 30 to 35 mL of buffer 1. The slow fraction was eluted with 20 to 25 mL of buffer 2 (1.4 mM sodium biphosphate, 46 mM sodium phosphate). The optical density of each fraction was measured at 415 nm after fivefold dilution of the slow hemoglobin fraction. The amount of glycosylated hemoglobin was expressed as a fraction of the total eluted hemoglobin. Our normal range for glycosylated hemo-

†The range was 19 to 92 μg/sq m/24 hr (n = 10).

globins measured by this method (6.2% ± 1.0%) is in close agreement with the range obtained by other groups.[11,12] Patients judged clinically to be in fair or poor control had a mean glycosylated hemoglobin concentration of 15.2% ± 1.5%.

Serum free and total insulin concentrations were measured according to the method of Nakagawa et al,[13] except that the volumes used were one fifth those employed in the originally described assay. Urine glucose concentration was estimated with copper sulfate tablets (two-drop Clinitest method).[14] Serum insulin levels were measured by a modification of the double-antibody method of Morgan and Lazarow.[15]

Mean values of serum insulin (μU/mL) and C-peptide (ng/mL) levels were computed for each period of urine collection in normal subjects. Similar calculations were made for the duration of the three-hour glucose tolerance tests in three diabetic patients. A best-fit line and correlation coefficient relating serum to urine C-peptide levels were computed using data from all control subjects (inset, Fig 1).

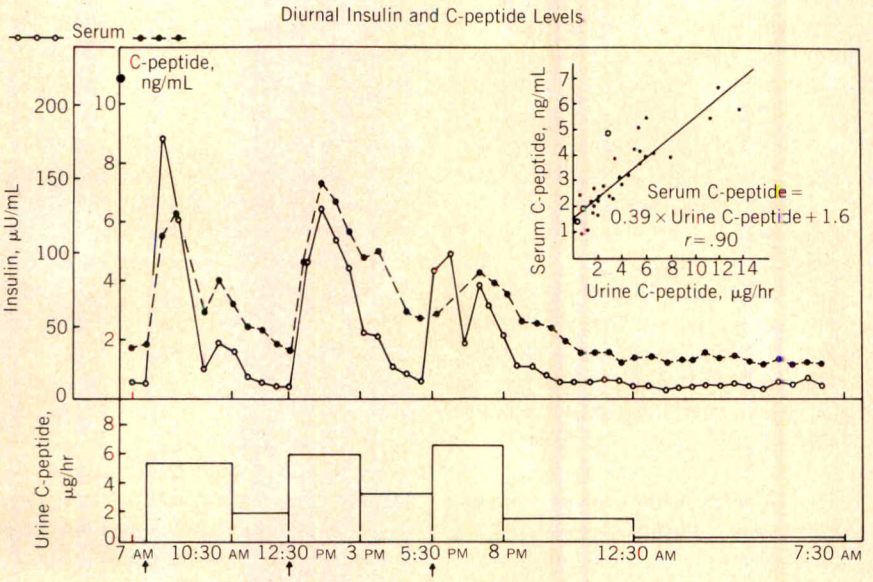

Fig 1.—Representative 24-hour profile of control subject's serum insulin and C-peptide concentrations and urinary C-peptide excretion. Arrows designate meal times. Inset, Relationship of mean serum C-peptide level to hourly urinary C-peptide excretion of control subjects (closed circles) and of three diabetic children (open circles) ($P < .001$).

RESULTS

Control Subjects

In the six adults, urinary C-peptide excretion rose sharply immediately after meals, diminished during postabsorptive periods, and for each period studied correlated well with the mean serum C-peptide concentration (Fig 1). The ten children had a mean urinary C-peptide excretion of 39 μg/sq m/24 hr, with a range of 19 to 92 μg/sq m/24 hr.

Juvenile Diabetic Patients

For the three patients who underwent oral glucose tolerance tests, points representing urinary C-peptide excretion during the three-hour test plotted against mean serum C-peptide concentration during the same period correlated well with data obtained from the control subjects (inset, Fig 1). In addition, serum insulin and C-peptide levels rose and fell synchronously throughout the test.

All patients with ketoacidosis were initially treated with continuous low-dose insulin infusions (< 0.1 units/kg/hr). Within 24 hours, they were

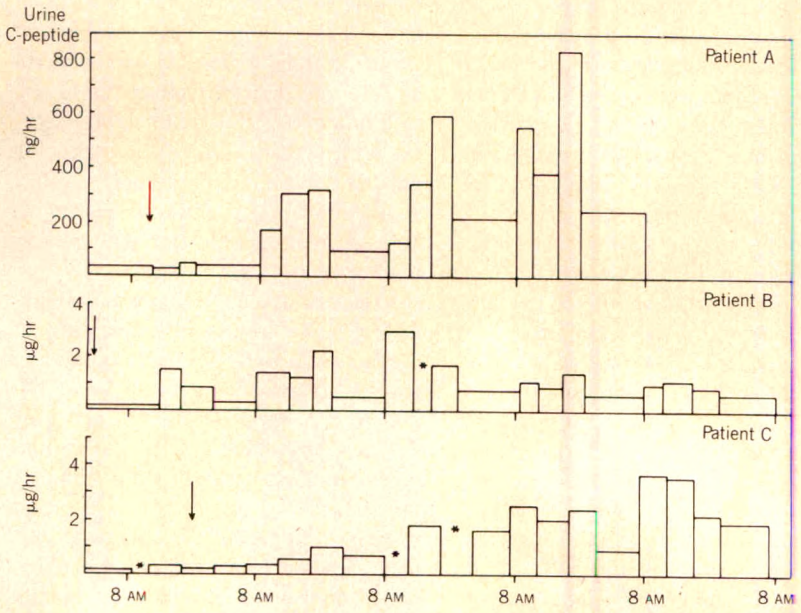

Fig 2.—Urine C-peptide excretion during and following therapy for diabetic ketoacidosis in three patients. Arrows indicate clearing of urine ketones and resumption of normal diet. Asterisks designate times when no urine was obtained.

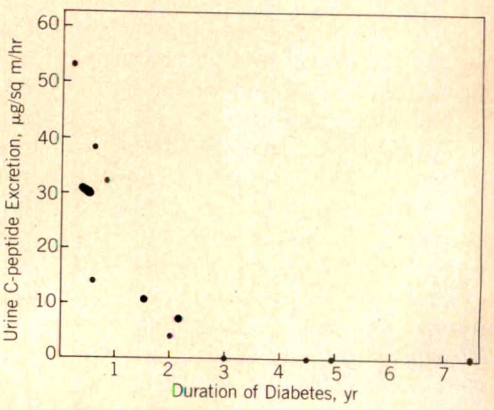

Fig 3.—Relationship of 24-hour urinary C-peptide excretion to duration of clinical diabetes mellitus.

eating meals normally and receiving intermittent subcutaneous short-acting, or a combination of short- and intermediate-acting, insulin. Urinary C-peptide excretion rose within 24 to 48 hours after the initiation of therapy (Fig 2). All subjects demonstrated higher urinary C-peptide excretion during the day, when they were eating, than during overnight periods of fasting. With resolution of ketoacidosis, the meal-related changes in excretion of C-peptide demonstrated in control subjects were reestablished in the diabetic patients.

In nine patients studied, 24-hour urinary C-peptide excretion was related to insulin dose and duration of diabetes. Of four patients receiving insulin doses of 27 to 47 units/sq m/24 hr, three had negligible urinary C-peptide excretion (Table). One (patient 4) had a measurable but low urinary C-peptide excretion of 4.5 μg/sq m/24 hr. All of these four patients had diabetes of relatively long duration (Fig 3). The remaining five patients were receiving low doses of insulin, 11 to 15 units/sq m/24 hr. Four of these had measurable urinary C-peptide excretion. Measurements of three were in the same range as those of the control subjects studied. The remaining patient (5), who differed from the others in that he had diabetes of long duration, had negligible urinary C-peptide excretion (Table).

Creatinine clearance was normal in two of the eight patients in whom it was measured. Two patients (1 and 9) had elevated creatinine clearances, and four patients (2, 4, 5, and 7) had slightly diminished creatinine clearance compared with age-appropriate normal values (Table).[16] There was no correlation between creatinine clearance and C-peptide excretion.

Serum free and total insulin concentrations were measured in eight of the nine patients to obtain a qualitative estimate of insulin-binding antibodies. Four of the five patients with diabetes of long duration had high serum total insulin values indicative of substantial insulin-binding antibodies. The fifth child (patient 5) had a lower serum total insulin value and required an insulin dose of only 15 units/sq m/24 hr (0.6 units/kg/24 hr). Of the four patients with clinical diabetes of less than one year's duration, serum total insulin concentration was measured in three. All had levels much lower than those found in patients with clinical diabetes of long duration (Table).

COMMENT

In normal and diabetic subjects in this study, mean serum C-peptide concentrations correlated well with simultaneous urinary excretion of C-peptide. Measurement of urine C-peptide in two- to three-hour collections reflected acute changes in β-cell secretory response to meals. Thus, assessment of urinary C-peptide excretion provided a potentially useful measure of β-cell activity.

We applied this technique to two groups of patients: three patients with diabetic ketoacidosis and nine well-controlled juvenile diabetics. In the first group, studied longitudinally during and immediately after episodes of ketoacidosis, there were substantial increases in urinary C-peptide excretion within 24 to 48 hours after correction of ketoacidosis. Although collection periods were not optimal for revealing acute, meal-related increases in urinary C-peptide excretion, there were fluctuations in urinary C-peptide levels in all three patients, with generally higher values during the day, when all were receiving three meals and three snacks, than during the overnight fasting periods.

In the second group, we found that measurement of urinary C-peptide excretion may be useful in assessing the role of endogenous insulin production as a determinant of insulin requirements. In the patients studied, urinary C-peptide levels in or near the normal range were related to low exogenous insulin requirements. Patients with low or negligible urinary C-peptide excretion had higher insulin requirements. However, patient 5, who had had diabetes for three years, had negligible urinary C-peptide excretion yet required relatively little exogenous insulin. He differed from the other subjects with diabetes of long duration and evidence of little or no endogenous insulin production in that he had a low level of insulin-binding antibodies. Thus, both insulin-binding antibodies and endogenous insulin appear to influence the dose of insulin required to maintain good diabetic control.

Endogenous insulin production has been postulated to influence exogenous insulin requirements and metabolic stability of juvenile diabetic patients.[2,3,17] It has been further proposed that measurement of serum C-peptide levels may aid in the management of juvenile diabetics.[18] Measurement of urinary C-peptide may be even more useful since urine collections can be done in patients' homes. For example, a patient complaining of frequent hypoglycemic episodes may have substantial endogenous insulin production and be receiving an excessive dose of exogenous insulin. Endogenous insulin production could be estimated over a 24-hour period or during the times of the hypoglycemic episodes by measurement of urinary C-peptide excretion.

Glycosylated hemoglobin determinations were used to substantiate the selection of patients for good diabetic control.[12,19] Seven of nine patients had glycosylated hemoglobin values below the mean value for patients judged to be in fair to poor control, 15.2% ± 1.5%. In addition, the selected patients' glycosylated hemoglobin values were less than the published means for juvenile diabetics of 12%[11] and 13.2%.[12] Some patients judged clinically to have been in good control and found to have minimal glucose spill had glycosylated hemoglobin levels of 8%, within 2 SDs of the mean for normal subjects. Good diabetic control was achievable in children both with and without substantial endogenous insulin production.

Recent studies[20-22] suggest that hyperglycemia results in exhaustion of β-cell secretion, further impairing glucose metabolism. Some have hypothesized that prompt, vigorous therapy of diabetic ketoacidosis as well as strict glucose control can enhance β-cell function and promote at least transient remission of diabetes.[5,23] It is possible that diabetic ketoacidosis per se suppresses insulin secretion and that correction of this metabolic derangement allows recovery of β-cell

function, a hypothesis compatible with the data from the three patients with ketoacidosis.

Measurement of urinary C-peptide excretion is a reliable index of β-cell function. Collections over short periods provide valuable data on short-term changes in insulin secretion. Since urine collections are easy to obtain in or out of the hospital, measurement of urine C-peptide excretion is an ideal method for longitudinal studies of β-cell function in diabetic patients. Such studies may also facilitate evaluation of newly available portable devices for continuous insulin delivery.[24-27]

Studies of control subjects were done in the General Clinical Research Center, University of Minnesota Hospitals, Minneapolis, and were supported by grant RR400 from the National Institutes of Health. Studies of control and diabetic subjects were supported by grant 0693-5872 from the Minnesota Medical Foundation. Dr Rappaport was the recipient of the Walter R. and Ruth L. Ramsey Postresidency Fellowship, 1977-1978.

The nursing staffs of stations 32 and 56 of the University of Minnesota Hospitals, as well as the nursing and laboratory staffs of the Minneapolis Children's Hospital, assisted in studies of diabetic patients. Nancy Boyum also assisted in organizing and conducting this study. Mary Stahlmann, Carole Pesek, and Lois Schorle provided technical assistance. Roxanne Esslinger provided editorial assistance and, with Edith Cusher, provided secretarial assistance. David R. Brown, MD, Frederick C. Goetz, MD, and David M. Brown, MD, referred patients to this study.

Acute Pulmonary Exacerbations in Cystic Fibrosis

A Double-blind Trial of Tobramycin and Placebo Therapy

Raoul Wientzen, MD; Claude B. Prestidge, MD; Robert I. Kramer, MD; George H. McCracken, MD; John D. Nelson, MD

• To determine the effect of antimicrobial therapy on acute pulmonary exacerbations in cystic fibrosis, a randomized, double-blind trial of tobramycin and placebo was carried out. Clinical responses were satisfactory in all 11 children given tobramycin and in seven of 11 given placebo. Two patients in the placebo group died. No patient given placebo had improved results on pulmonary function studies, whereas improvement of 15% or more occurred in four of the six patients given tobramycin who could cooperate with the testing. Quantitative cultures of sputum showed a decrease of 1 logarithm or greater in *Pseudomonas* sp concentrations in six of seven patients in the tobramycin group and in two of eight in the placebo group. No difference in staphylococcal colonization was found. Several features indicate that children with severer disease were randomly assigned to the placebo group; nevertheless, the trend toward improved response in patients given tobramycin suggests that empirical therapy with antibiotics is beneficial for patients with acute pulmonary exacerbations in cystic fibrosis.

(*Am J Dis Child* 134:1134-1138, 1980)

Gram-negative bacilli, chiefly *Pseudomonas* sp, and *Staphylococcus aureus* frequently infect the lower respiratory tracts of patients with cystic fibrosis (CF). For several reasons, the role these organisms play during acute exacerbations of pulmonary disease is equivocal. They are as likely to be present during asymptomatic intervals as during periods of pulmonary deterioration. Antimicrobial therapy during periods of pulmonary exacerbation rarely eradicates the organisms from the tracheobronchial tree, and eradication is not necessary for regression of pulmonary symptoms. Systemic infection with these potential pathogens is rare, even in the most debilitated patients. The improved longevity that patients with CF now experience is possibly due as much to scrupulous attention to pulmonary toilet and nutrition as it is to the use of antibiotics. Finally, to our knowledge, no controlled studies have been performed to evaluate the role of therapy with antibiotics in acute pulmonary exacerbations of CF.

MATERIALS AND METHODS

Patient Populations

Between April 1976 and June 1977, pediatric patients admitted to Children's Medical Center, Dallas, because of acute pulmonary exacerbation of CF were included in the study after informed parental consent was obtained. Patients were excluded from study if they were judged to have life-threatening illness or had empyema, pneumothorax, liver failure, or systemic infection. In addition, patients were removed from the study if bronchoscopy or bronchial lavage was required during hospitalization.

Therapy

On admission to the study, patients were assigned by a list of random numbers to receive either tobramycin or placebo. Tobramycin, 2 mg/kg, was given every eight hours as a one-hour continuous infusion. The placebo was a lactose solution prepared by Lilly Research Laboratories, which was administered in an identical fashion. Therapy was continued daily until the time of discharge from the hospital or until persistence or worsening of symptoms required breaking the code.

In addition to placebo or tobramycin, all patients admitted to the study received intensive chest physiotherapy administered in a standard fashion four times a day. Parenteral and oral hydration therapy, bronchodilators, and oxygen were given when needed.

Pharmacokinetic Evaluation

Pharmacokinetic evaluation of most of the patients given tobramycin was performed on the third hospital day. Blood for the tobramycin assay was collected one and six hours after the one-hour infusion of the drug. Serum was separated and frozen at −70 °C until the assay was performed. Concentrations of tobramycin in serum were measured by the micromethod of Simon and Yin,[1] using *Bacillus subtilis* as the test organism. Sputum specimens for tobramycin assay were collected one and eight hours after the dose. A homogenized mixture of sputum and 2% *N*-acetyl-L-cysteine (NAC) was prepared in a ratio of 1 mL of NAC to 1 g of sputum, centrifuged at 4 °C for 20 minutes at 12,000 rpm, and the supernatant assayed for tobramycin concentration. This concentration of NAC did not affect the assay organism. Known concentrations of tobramycin added to sputum of patients with CF who were not receiving antibiotics were simultaneously assayed as control specimens. Sputum was collected from study patients before administration of the first dose of tobra-

mycin and assayed for the presence of inherent antibacterial activity, and this amount was subtracted from the tobramycin assay.

Bacteriologic Studies

Quantitative cultures of sputum were obtained from patients old enough to provide expectorated specimens. This was done after 15 minutes of intensive chest physiotherapy before the first dose of tobramycin or placebo and then at four- to six-day intervals. Sputum for bacterial measurement was frozen at −20 °C for two minutes and carefully separated from saliva. One gram of frozen sputum was liquified by the addition of 1 mL of a 2% solution of NAC and homogenized for one minute at 9,000 rpm in an agitator. Serial tenfold dilutions of this homogenate were prepared in brain-heart infusion broth and plated in duplicate on 5% sheep blood agar and eosin-methylene blue agar plates. Identification of organisms was by standard bacteriologic methods. Results were expressed as the number of colony-forming units (CFU) per gram of sputum.

Strains of *Pseudomonas* and *S aureus* isolated from cultures of sputum were tested for tobramycin sensitivity by Mueller Hinton agar plate dilution, using a bacterial inoculum of 10^4 CFU/mL.

Clinical Evaluation

Clinical evaluation was carried out by one of two physicians (R.I.K., C.W.P.) who were unaware of the patient's parenteral therapy. Twice-daily review of the patients' progress included noting the general level of activity, appetite, personality, disposition, a description of the amount, thickness, and ease of production of sputum, and the Schwachman score. In addition, the patients' weight, body temperature, oxygen requirements, and resting pulse and respiratory rates were recorded. Chest roentgenograms were performed at the times of admission to the study and discharge, and were interpreted by a radiologist who had no knowledge of the patients' treatment. Vital capacity (VC), peak expiratory flow rates (PEFR), and forced expiratory volume at 1 s (FEV_1) were evaluated at the time of admission to the study and at five-day intervals in children old enough to comply with the techniques. There is a reproducibility error of 5% to 10% with these tests; therefore, a change of 15% or more with time was considered significant.

Statistical Analysis of Data

Student's t test and Fisher's exact test were used to test for differences between the two treatment groups in patient characteristics such as age, sex, roentgenographic pulmonary changes, etc. The z test with two proportions[2] was used to test for differences between the groups in clinical and laboratory responses to therapy.

RESULTS

Patient Characteristics

Twenty-two patients were admitted to the study and received 24 courses of therapy, 12 each of tobramycin and placebo. Two patients were admitted to study on two separate occasions after intervals of three or four months and received, by random assignment, therapy that was different from the initial treatment.

Table 1 gives the pertinent characteristics of the two treatment groups. Patients given placebo tended to be younger, to have more severe roentgenographic pulmonary changes, to have greater reversal of the normal albumin-globulin ratio, and to require more hospitalizations for pulmonary infection, and were more likely to be free of colonization with *S aureus* than were the patients given tobramycin. None of these differences was statistically significant, although the difference between the two groups in number of hospitalizations ($P > .5$) and prevalence of *S aureus* ($P = .11$) approached significance.

Mean initial colony counts of 1.2×10^8 CFU of *Pseudomonas* sp per gram of sputum in the placebo group exceeded by almost 2 logarithms the mean initial counts found in the tobramycin group. Conversely, the mean initial number of CFU of *S aureus* in the placebo group was 2 logarithms lower than those found in the tobramycin group (2.2×10^6 vs 2.2×10^8 CFU/g of sputum).

Clinical Response

The clinical responses to therapy are given in Table 2. Two children, one in each group, could not be evaluated. One was withdrawn from the study after three days of therapy with placebo at the parents' request and one completed five days of therapy with tobramycin, but inadequate clinical data were recorded. All of 11 patients given tobramycin had satisfactory clinical responses, whereas only seven of the 11 placebo-group patients had a comparable response. Deterioration of

Outcome of Therapy	Placebo, 12 Patients	Tobramycin, 12 Patients
Satisfactory	7	11
Unsatisfactory	4	0
Died	2	0
Unevaluable	1	1

the clinical status required the removal from the protocol of three children given placebo. Two of these were subsequently given antibiotics and had satisfactory clinical outcomes. The third patient was removed from study after two days of therapy with placebo and subsequently died after two days of treatment with gentamicin sulfate. The fourth patient with unsatisfactory outcome died after 24 hours of therapy with placebo. The difference in outcome between the two treatment groups borders on statistical significance ($P > .5$) (z test with two proportions).

Laboratory Findings

Table 3 gives the pertinent respiratory and bacteriologic responses to therapy in the two groups. No patient given placebo demonstrated improvement in pulmonary function studies, whereas four of six children given tobramycin showed 15% or greater improvement in at least two of the three tests performed (VC, FEV_1, PEFR). This difference in pulmonary function was statistically significant ($P < .05$) (z test). Chest roentgenograms showed no consistent changes in most patients in either group during the course of treatment with placebo or tobramycin.

In patients given placebo, the bacterial concentrations in sputum ranged from 4.6×10^6 to 9.5×10^8 CFU/g of sputum for *Pseudomonas* sp and from 9.1×10^4 to 5.8×10^6 CFU/g for *S aureus*. The range of bacterial counts for the tobramycin group was from less than 10^2 to 4.4×10^6 for *Pseudomonas* sp and from 9.6×10^5 to 1.7×10^9 for *S aureus*. Tobramycin treatment was associated with a 1 logarithm or greater decrement in *Pseudomonas* sp concentrations in sputum of six of seven patients, although this occurred in only two of

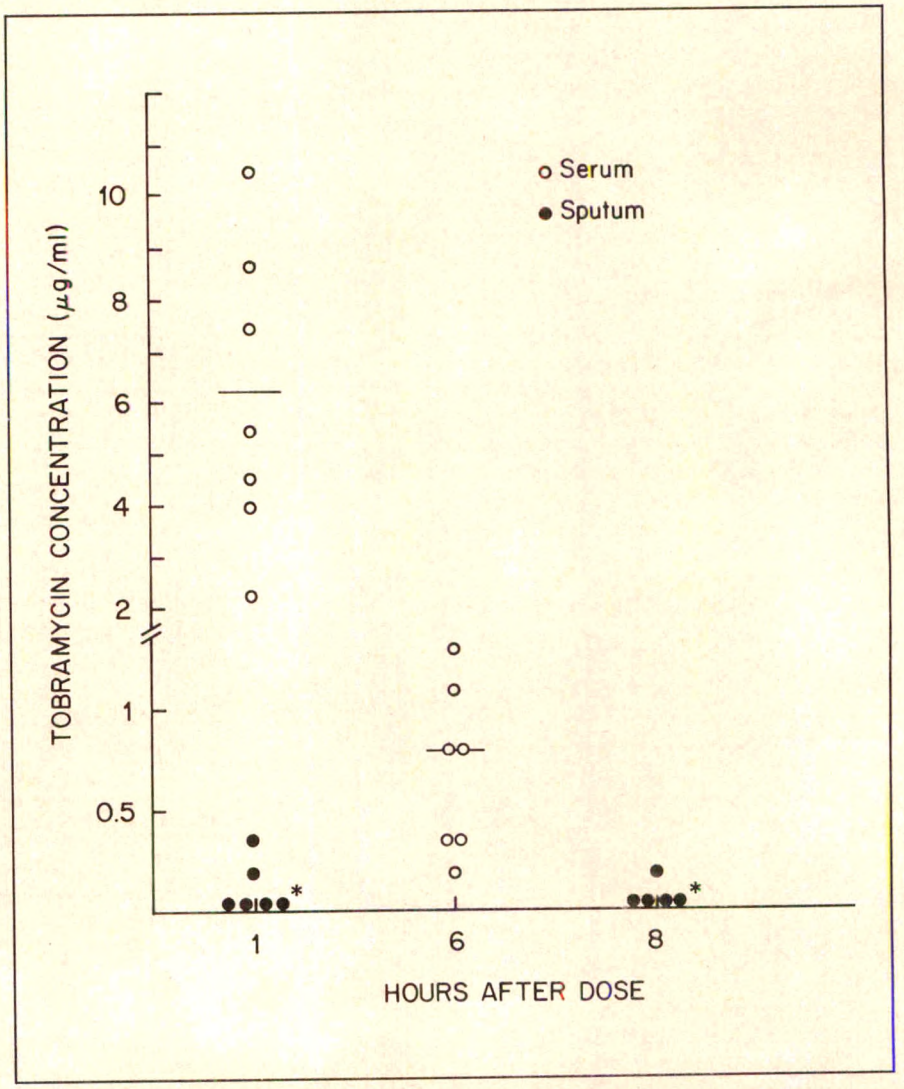
*Consistent change of at least ±15% in two of three tests (vital capacity, peak expiratory flow rates, and forced expiratory volume at 1 s).



Concentrations of tobramycin in serum and sputum from seven patients. Specimens indicated with asterisk were below lower limit of sensitivity of assay (0.2 μg/g).

eight patients given placebo. The one patient in the tobramycin group who did not show a significant decrease in *Pseudomonas* concentration had colony counts of 3.6×10^5 on day 1 of therapy and 4.4×10^4 on day 10. The changes in *Pseudomonas* colony counts for the two therapy groups was of borderline significance ($P > .5$). There were no differences between the two groups with respect to the changes in colony counts of *S aureus*.

The Figure presents the concentrations of tobramycin in sputum and serum. The mean serum tobramycin concentrations at one and six hours after the dose were 6.2 and 0.7 μg/mL, respectively. These concentrations exceeded the mean minimal inhibitory concentrations (MIC) of 0.46 and 0.24 μg/mL for five strains of *S aureus* and nine strains of *Pseudomonas* sp, respectively, obtained from study patients. Isolates of *Pseudomonas* sp and *S aureus* obtained on days 5 or 10 of therapy remained susceptible to tobramycin. Concentrations of tobramycin in sputum at one and eight hours after intravenous (IV) administration of the drug were less than the lower limit of the assay (0.2 μg/g) for four of six peak and four of five trough specimens. Concentrations of 0.3 to 0.2 μg/g were achieved in sputum of three patients.

Nephrotoxicity was not encountered in the patients given tobramycin.

COMMENT

The outcome of acute pulmonary exacerbations of CF reflects many independent variables that operate simultaneously: the waning with time of intercurrent viral infection,[3] hydration and nutritional support, aggressive chest physiotherapy and postural drainage,[4] and antimicrobial therapy. Our study attempted to evaluate the contribution of this last variable. The clinical response to therapy with tobramycin tended to be favorable when compared with treatment with placebo, but this difference was only of borderline statistical significance. This trend is supported by the significant improvement in the tobramycin group in sequential pulmonary function studies and by the greater reduction in sputum colony counts of *Pseudomonas* sp. In addition, two patients initially given placebo died after one and four days of hospitalization. Although it is possible that antimicrobial therapy may not have prevented either death, these early adverse outcomes occurred in a study in which the participants were observed closely and that excluded patients judged by experienced physicians to have life-threatening pulmonary exacerbations.

Most published studies of therapy with antibiotics for CF,[5-7] although suggesting clinical benefits to its use, have failed to include control groups for analysis, even after the skepticism voiced almost a decade ago.[8] Consequently, there are few studies of CF that resemble the present work closely enough in design to allow comparisons. A double-blind trial of therapy with continuous oral cloxacillin sodium or placebo given on an ambulatory basis for 12 months to 22 patients with CF was carried out by Denning et al.[9] Statistical analysis of results is not reported, but there was less progression of pulmonary disease as evaluated by chest roentgenograms, pulmonary function studies, and blood gas determinations in the group given antibiotics. Similar beneficial effects of long-term therapy with antibiotics for patients with CF have been reported by Loening-Baucke and coworkers,[10] who demonstrated improved weight gain and significant decrease in the number and severity of respiratory illnesses for patients infected with *S aureus* and treated with cephalexin monohydrate. Although suggesting a role for continuous therapy with antibiotics in the suppression of the chronic bronchitis of the ambulatory patient with CF, these studies do not address the question of the efficacy of antimicrobial therapy for acute pulmonary exacerbation in the hospitalized patient.

In a randomized but nonblind study, Beaudry and co-workers[11] compared the effectiveness of therapy with parenteral cloxacillin alone or with carbenicillin plus gentamicin for acute pulmonary flare-ups in 22 patients with CF. Children in both treatment groups had *P aeruginosa* as the predominant respiratory flora. No difference was found between clinical outcomes of the two groups, which led the authors to question the justification of anti-*Pseudomonas* therapy.

If antimicrobial therapy had a beneficial influence on the bacteriologic course of disease in our patients, efficacy was not a function of tobramycin levels in sputum. In only three of 12 determinations were detectable amounts of tobramycin found, and two of these three had amounts below the mean MIC for both the staphylococcal and *Pseudomonas* isolates tested. Penetration of tobramycin into bronchial secretions has been studied in other experimental settings, with results different from ours. In the dog, mean peak tobramycin concentrations in bronchial secretions of 1.15 μg/mL were detected two hours after IV administration.[12] In adult patients without CF, the mean tobramycin concentration of 3.75 μg/mL in bronchial secretions approached 67% of the concomitant serum levels when calculations were based on bronchial secretion standards.[13] However, when concentrations were calculated from the serum standards, the values were less than 1 μg/mL. The difference between the scant concentrations of tobramycin in sputum from our patients and the considerably higher levels reported by others may be due to a variety of factors. These include the type of standard curve used in calculations, the method of collection of the secretion (bronchoscopy and intubation vs expectoration), and the much larger volume of bronchial secretions produced by infected patients with CF that acts to dilute the amount of tobramycin reaching the airways. In a small group of patients with CF, McCrae et al[7] found a mean tobramycin level in sputum of 0.4 μg/mL after a parenteral dose of 2 mg/kg. In that study, which used a bioassay with *Pseudomonas* as the test organism, the method of sputum preparation was not outlined, nor is it certain that inherent anti-*Pseudomonas* activity of sputum was taken into account. For therapy for CF, high sputum concentrations of antibiotic may be an attractive artifact and not a necessary

condition for clinical and bacteriologic improvement, as was suggested by the present study. More important to effective therapy than concentration of antibiotic in sputum may be the concentration of antibiotic perfusing the bronchial mucosa.

Little effort has been devoted to the study of the quantitative bacteriology of the sputum of patients with CF. Mischler et al[14] reported bacterial counts of 10^6 to 10^8 CFU/mL of sputum for *S aureus* and 10^4 to 10^8 CFU/mL for *P aeruginosa* in nine patients with CF who had acute pulmonary exacerbations; these levels are similar to those found in our study. These investigators[14] documented significant reduction in the concentration of *S aureus* during therapy with antibiotics (type unspecified), but were unable to show a concomitant decrease in the concentration of *Pseudomonas*. By contrast, all but one of our patients given tobramycin had at least a 1-logarithm decrease in *Pseudomonas* colony counts, and in half of these decreases of 2 logarithms were found. Eradication of *Pseudomonas* was achieved in one patient. This was not the case with *S aureus*, where only two of seven patients who received tobramycin experienced greater than 1-logarithm decreases in colony counts.

Although strict statistical significance is lacking, the results of this study suggest that outcome of acute pulmonary exacerbation of CF is benefited by the use of antimicrobial therapy. However, this interpretation of the results of the present study is complicated by two factors. First, the relatively small number of patients in each treatment group makes statistical analysis difficult. Second, the placebo and tobramycin groups, though chosen randomly, were not strictly comparable. Several characteristics of the placebo group suggest that these patients may have had more advanced disease than did those in the tobramycin group.

Placebo-group patients harbored significantly greater numbers of *Pseudomonas* organisms in the tracheobronchial tree than did those in the tobramycin group, and fewer patients in the placebo group had concomitant staphylococcal colonization. Kulczycki et al[15] have recently suggested that exclusive, heavy *Pseudomonas* infection may correlate with greater severity of disease and worsened prognosis. Other characteristics of the placebo group that suggest more severe underlying disease include a greater number of prior hospitalizations for pulmonary problems, a greater likelihood of severe disease on chest film, and greater reversal of the albumin-globulin ratio.

It is possible, therefore, that the apparently favorable response to therapy with tobramycin may have reflected the natural history of the disease in the less severely affected patient, rather than the effects of antimicrobial therapy. Additional investigation may be needed to clarify this question. Until such new data are forthcoming, it is advisable to continue to use empirical antimicrobial therapy for respiratory exacerbations of CF.

Helen Kusmiesz, RN, assisted with collection of specimens and clinical records.

Menarchal Determinants in Cystic Fibrosis

Thomas Moshang, MD, Douglas S. Holsclaw, Jr, MD

• Age, derived fat index (FI), and clinical score at the time of menarche were determined from records of 63 girls with cystic fibrosis (CF) and from 17 comparably aged but nonmenarchal girls with CF. The mean age of menarche in girls with CF was 14.5 years at a mean FI of 20.1% fat; thus, they were significantly older and had less fat than normal girls. Menarchal age was related to severity of illness. Amenorrheic girls with CF, mean age of 14 years, were significantly sicker and smaller. Gonadotropin and estradiol levels in 23 girls with CF were normal. The delay in menarche in CF appears to be closely related to severity of illness. Furthermore, although the relationship of puberty to body composition may or may not be coincidental, it is unlikely that puberty is initiated by a "critical body composition."

(*Am J Dis Child* 134:1139-1142, 1980)

Data from the Cystic Fibrosis Foundation Registry indicate that the majority of patients with cystic fibrosis (CF) will survive their teen years.[1] Not surprisingly, a major concern of this enlarging population of adolescents relates to their sexual development. Delay in sexual development is recognized as a significant, although not universal, complication of CF.[2,3] The study of factors involved in the sexual maturation of patients with CF may provide information useful not only for therapeutic benefits and emotional relief for patients by allowing for anticipatory counseling but also may provide further insight into some of the physiologic factors controlling the onset of puberty.

Puberty obviously is a complex maturational process involving changes in secretions of neuroendocrine and gonadal hormones. The factors responsible for initiating changes in hormonal secretions and onset of puberty in human beings are still obscure. The hypotheses that pubertal events are secondary to maturational or time-dependent changes in the hypothalamus[4,5] do not explain the increased incidence of delay in sexual development in a number of illnesses, such as malnutrition, diabetes mellitus, and CF. Frisch and associates have proposed that the initiation of puberty is "triggered" by the attainment of a critical body composition, ie, a specific increase in fat in relation to lean body mass alters the metabolism of gonadal steroids, which in turn initiates the onset of development of secondary sexual characteristics.[6-8] Our present study of menarchal determinants in girls with CF supports the findings of Frisch and associates that menarche can be delayed by the lack of attainment of a critical body composition but also suggests that other factors are more directly responsible for initiation of puberty.

METHODS

Records of all female patients, both living and dead, registered at two regional CF centers were reviewed. Only those records that clearly documented the first menstrual period or clearly indicated the continued absence of menarche were used. For 63 menarchal girls with CF, the height, weight, and clinical assessment (clinical score) of severity of disease[9] noted at the visit most proximate (< three months) to the menarchal event were obtained. Similar data were abstracted from the most recent clinic visit of 17 girls with CF who were older than 12.5 years and still amenorrheic. Menarchal age and weight were obtained by history for the patients' sisters and mothers (not affected by CF) and documented by written record when possible.

Body composition (total body water [TBW] as a percentage of body weight [BW] and body fat [BF] as a percentage of BW) was derived from weight (kilograms) and height (centimeters) measurements with the following formulas[10-12]:

$$TBW = (-10.313 + 0.252\,[\text{weight}]) + 0.0154\,(\text{height})$$

$$\text{Lean body mass} = TBW/72$$

$$BF = BW - \text{lean body mass}$$

Since the components of body composition are reciprocally related, an increase in

the percent TBW must be accompanied by a corresponding decrease in the percent BF. For the remainder of this study, body composition will refer to the percent BF, called the "fat index."

Although these formulas were derived from measurements obtained from normal children and adults and may not be accurate when applied to patients with CF, similar derivations have been used in studies of bedridden and ambulatory mentally retarded children[13] and in comparisons of children with various disorders of sexual development to normal children.[14]

Twenty-three cases of living female patients with CF, aged 10 to 18 years, were evaluated in terms of pubertal development with the method of Tanner[15] and were segregated into the following groups: (1) completely prepubertal; (2) early adolescence; (3) late adolescence; and (4) adults. Early adolescence was defined as patients with mainly Tanner's 2 or 3 staging in the various areas of secondary sexual development. Late adolescence was confined to those patients with menarche and/or Tanner's 3 and 4 staging in most of the areas of secondary sexual development.

Serum samples were obtained from these patients for determination of levels of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and estradiol (E_2). Serum LH and FSH levels were determined by a double-antibody radioimmunoassay technique with a commercial kit (Radioassay Systems); values were reported as International milliunits per milliliter (Second International Reference Standard of Human Menopausal Gonadotropin [standard provided by Dr Bingham of Mill Hill, England]). Serum E_2 levels were determined by a double-antibody radioimmunoassay.[16]

RESULTS

A comparison of the physical data for girls with CF and the data of Frisch et al[7] for normal girls is summarized in the Table. The mean age for menarche in the girls with CF was 14.5 years. This value is similar to the finding of 14.2 years reported by both Stern et al[2] and Mitchell-Heggs et al[17] and exceeds the mean menarchal age of the patients' mothers (13.0 years), the patients' sisters (13.1 years), and normal girls (12.9 years).[7] The patients with CF also achieved menarche at a shorter height, lower weight, and lower derived fat index as compared with normal girls. Although the mean value for fat index for the 63 menarchal girls with CF was 20.1%, 13 of the 62 (20%) achieved menarche at a body composition less than the proposed critical body composition of 17% body fat (59.8% TBW/BW)[8] (Fig 1). Two of the patients with CF achieved menarche at a fat index composition of only 7%.

The Table also compares the clinical score of the menarchal CF females with a group of amenorrheic girls with CF of similar age. The amenorrheic girls were significantly sicker (as indicated by the clinical score) and shorter and lighter. The mean body composition of the amenorrheic patients was 11.7% BF, significantly below the mean value of 20.1% BF of the menarchal CF group and significantly less than Frisch and McArthur's proposed "critical" 17% BF.[8]

The correlation of age of menarche to severity of illness is shown in Fig 2. The more severe the illness is (lower clinical score) the more delayed is the onset of menarche ($r = -.43$, $n = 63$, $P < .01$).

The serum values for LH, FSH, and

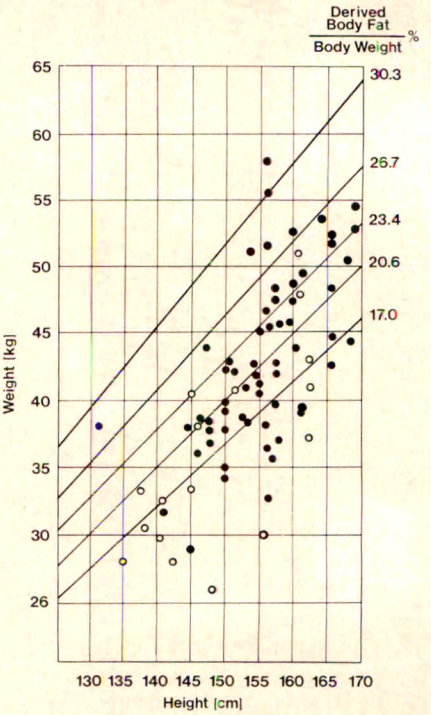

Fig 1.—Height and weight of menarchal patients with cystic fibrosis (CF) (solid circles) and primary amenorrheic patients with CF (open circles) are plotted on modification of graph designed by Frisch and McArthur.[8] Proposed minimal body fat content necessary for menarche is 17%.

E_2 were generally lower than the mean value for chronologic age for normal girls but were within the normal range (Fig 3). When the hormone values of girls with CF were plotted according to stage of pubertal development, FSH and E_2 values were comparable to values found in normal girls at corresponding stages. The LH values, however, remained in the lower ranges of normal, except in patients in group 4 (Fig 3). In general, the gonadotropin and E_2 levels for patients with CF are considered to be within the normal range.

COMMENT

Those factors primarily responsible for initiating puberty in human beings are still not fully defined. Frisch and her associates have hypothesized that body composition is an important determinant for the onset of puberty.[6-8] Other investigators have suggested that the changes in body composition during puberty are coincidental and secondary to gonadal hormone activity.[18] By excluding any

relationship of body composition to initiation of pubertal events, this viewpoint does not explain the decrease in gonadotropin levels or delay in development of secondary sexual characteristics during states of malnutrition or other illnesses.

In our study, patients with CF who were still amenorrheic despite having attained a fairly advanced chronologic age had advanced pulmonary disease and malnutrition. They had a mean body composition in which the derived fat index of 11.7% was significantly less than the minimally necessary 17% BF as proposed by Frisch and McArthur.[8] Although several of the amenorrheic patients with CF had body compositions with fat indices greater than 17%, Frisch has indicated that this proposed critical body composition is the minimal percent BF to be achieved before menarche ensues and that menarche can occur at greater fat indices. Our observations of the marked delay of menarche in CF, when correlated with the body composition data, would, at first analysis, tend to support the "Frisch" hypothesis.

However, the basis of the original hypothesis of Frisch et al[6,7] was the finding of an "invariant mean weight" at menarche in different populations of menarchal girls, including undernourished patients. Critics of this hypothesis included Johnson et al,[19] who noted that mean weight at menarche was not invariant among several different populations. The girls with CF achieved menarche at a mean weight of 43.8 kg, significantly less than normal girls. Frisch and McArthur[8] subsequently modified the hypothesis and proposed that puberty was initiated by attainment of a "critical" body composition, with the use of both height and weight to derive TBW and BF.

Nevertheless, using the same formulas to derive TBW and BF, we found the mean percent BF at menarche in CF to be 21.1%, significantly less than that in the normal girls. In fact, the distribution of individual body composition at menarche was shifted downward, so that only 17 of the 63 patients (20%) exceeded the mean value for percent BF of normal

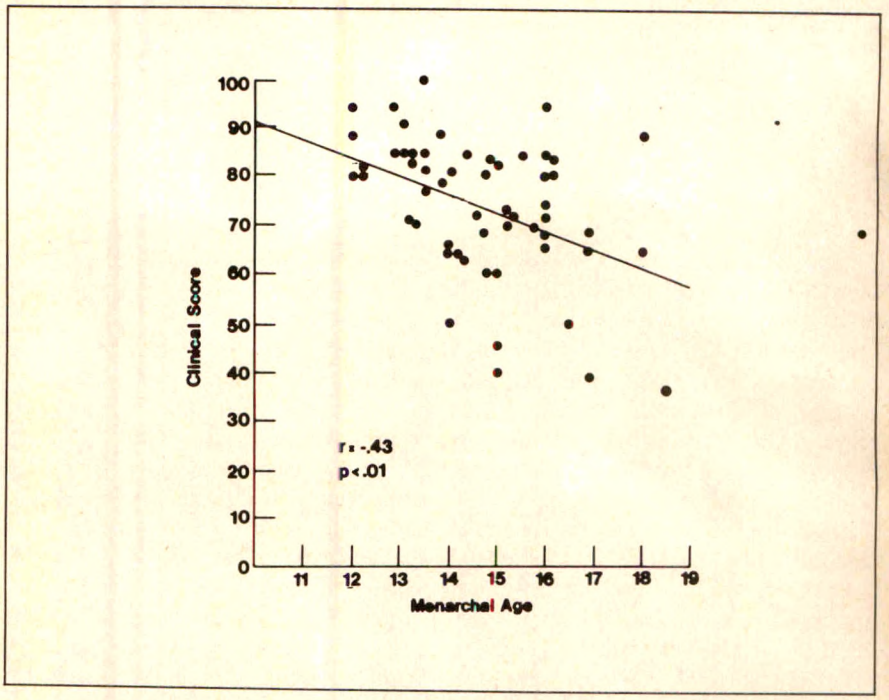

Fig 2.—Correlation of age of menarche to clinical score of patient at time of menarche in patients with cystic fibrosis.

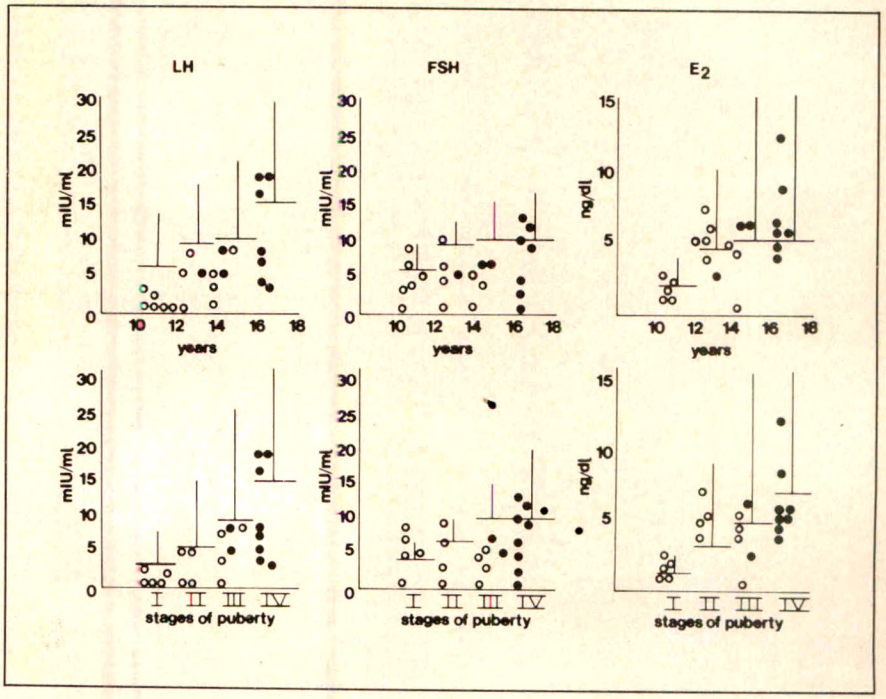
Fig 3.—Serum concentrations of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and estradiol (E_2) for 23 adolescent girls with cystic fibrosis (solid circles represent menarchal patients; open circles represent patients who are still amenorrheic) are plotted against age and sexual maturation. Mean value for normal girls in our laboratory is represented by horizontal bar. Perpendicular line represents normal values 2 SDs greater than mean.



girls and 20% achieved menarche with much less BF than the proposed critical 17%. Two of these latter patients achieved menarche with a derived fat index of 7% BF (and at older ages: 16.5 and 17.3 years). Although the findings in the amenorrheic girls with CF suggest that lack of attainment of a critical body composition may delay menarche, the body composition data of the menarchal girls indicate that other factors will eventually initiate puberty. In fact, the significant percentage of girls with CF achieving menarche at fat indices less than the proposed critical level would indicate that the primary factors responsible for initiating puberty are not fat content or body composition and that these factors can overcome in time any feedback control sensitive to inanition or body composition.

The Mellits-Cheek formulas used by Frisch and her associates and by us to calculate lean body mass, TBW, and BF were derived from studies in normal children. The use of these formulas in the studies of Frisch and associates has been criticized because of their inaccuracies, especially when applied to "abnormal" children, such as the undernourished children in the Alabama study.[20] Similarly, the possible inaccuracies of these formulas when applied to children with CF must be acknowledged. Forbes et al, with the use of ^{40}K counting, has noted that BF was subnormal in 50% of patients with CF.[21] Obviously, prospective studies relating body composition to puberty should use more accurate methods.

The gonadotropin and E_2 levels in our patients were within the range of values for normal girls, especially when correlated with sexual maturation. Serum LH levels, however, remained slightly lower than anticipated, except in the most physically mature girls with CF as compared with the normally distributed levels of FSH. Discordantly low LH values, as compared with FSH values, have been noted in anorexia nervosa.[22,23] The explanation for the low LH values in states of inanition is not known, although Warren[23] has suggested that the pituitary tropic cells for LH may be more sensitive to weight loss than the FSH gonadotroph. The normal serum levels of gonadotropins and estrogens in the more mature patients with CF, as well as the findings of Reiter and associates[24] of normal gonadotropin responses to gonadotropin-releasing hormone, indicate that there is no primary dysfunction in the hypothalamic-pituitary-gonadal axis in CF. The capability of a number of the girls with CF to become pregnant and carry their infants to term would also tend to substantiate this.

Our data suggest that the delay in pubertal development in girls with CF is closely related to the severity of their disease and nutritional status. The healthier female adolescents with CF can certainly be reassured of their eventual sexual maturation. Furthermore, our study suggests that the interrelationship between body composition and puberty may not be a coincidental relationship and that the neuroendocrine mechanisms controlling onset of puberty can be modified by various factors, including inadequate fat reserve. However, the significant percentage of girls with CF with low fat indices achieving menarche, albeit often very delayed, indicates that body composition is not the factor that directly initiates onset of puberty.

This study was supported in part by a clinical research grant from the Cystic Fibrosis Foundation and a Pediatric Pulmonary Center grant from the Maternal and Child Health Program, Bureau of Community Health Services, Department of Health, Education, and Welfare.

Rose Frisch, MD, reviewed this manuscript and allowed us the use of her normative data and the graph design used in Fig 1 of our paper. Kathryn Chance, MD, Christa Habboushe, MD, Helen Keith, MD, and Judy Palmer, MD, helped in obtaining some of the patient data. Nancy Huang, MD, Director of the Cystic Fibrosis Center at St Christopher's Hospital, Philadelphia, allowed us to review her patient records for inclusion in this study. Technical assistance was provided by Fran Valeo.

Intravenous Aminophylline in Patients With Cystic Fibrosis

Pharmacokinetics and Effect on Pulmonary Function

Gary L. Larsen, MD; Roger J. Barron, MD; Ronald A. Landay, MD; Ernest K. Cotton, MD; Mario A. Gonzalez, PhD; John G. Brooks, MD

• Intravenous aminophylline was administered to ten patients with cystic fibrosis (CF) to determine if the medication would improve pulmonary function and to study theophylline pharmacokinetics. Intravenous normal saline was given on another day as a control. Thoracic gas volume and airway resistance, measured in a volume displacement body plethysmograph, and maximal expiratory flow-volume curves were performed before and after each infusion. No significant improvement was noted in pulmonary function after normal saline infusion. Following aminophylline infusion, significant improvement in thoracic gas volume, residual volume, specific airway conductance, and maximal expiratory flow at 60% of total lung capacity was noted. The pharmacokinetic analysis revealed a mean half-life of 4.7 hours, a total clearance of 91 mL/hr/kg, and a volume of distribution of 574 mL/kg. Intravenous aminophylline can acutely decrease airway obstruction in children with CF.

(*Am J Dis Child* 134:1143-1148, 1980)

The effect of methylxanthines on pulmonary function in patients with cystic fibrosis (CF) has been examined in one previous study, and theophylline was found to have limited usefulness when given orally over a four-week period.[1] We have assessed the short-term effects of intravenous (IV) aminophylline on pulmonary function in ten patients with CF and have found significant decreases in airway obstruction after the medication. In addition, the pharmacokinetic parameters of half-life, total clearance, and volume of distribution have been determined for each patient and for the group, and the results have been compared with published values for children with asthma.

PATIENTS AND METHODS

Ten children with CF were selected to be subjects for this study based on their ability to perform the required pulmonary function tests and willingness to participate in the study. Each patient had a forced expiratory volume in 1 s to forced vital capacity (FVC) ratio of less than 75%, indicating obstructive lung disease. The diagnosis of CF in all children was based on a sweat chloride concentration greater than 70 mEq/L with a consistent clinical and/or family history. In this study, there were six girls and four boys ranging in age from 10 to 18 years (Table 1). Their clinical National Institutes of Health (NIH) scores reflected mild to moderately severe disease.[2] An allergy profile for the patients showed that five had a clinical history compatible with allergic rhinitis, two had a history of at least one episode of wheezing, and nine had at least one positive skin test to common aeroallergens as determined in a previous prospective study.[3]

Each patient was studied on two separate days, when there was no clinical evidence of acute change in pulmonary status and no history of upper respiratory infection for a period of at least six weeks. On the first day, each patient was given a single dose of IV aminophylline equivalent to 4.0 mg/kg of theophylline (anhydrous) over five minutes. Because the study was also designed to measure theophylline kinetics in the subjects, and this required two IV lines and multiple blood samples totaling approximately 30 mL over eight hours, the patients knew they were receiving aminophylline. On the second study day, an equal volume of normal saline was given intravenously during a five-minute period. This part of the study was single-blind. Each patient was told he would receive either IV aminophylline or normal saline. All ten subjects, however, received normal saline so that the results of the pulmonary functions after the saline infusion could be compared with the results after aminophylline infusion. Thus, each child served as his own control. The patients and their parents gave informed consent before the study was performed.

On each study day, pulmonary function was tested before and 1, 3, and 5 hours after the infusion. A volume displacement body plethysmograph[4] was used to measure thoracic gas volume (TGV) and airway resistance,[5,6] and maximal expiratory flow-

volume curves were obtained with an electronic spirometer. Peak expiratory flow rate, together with maximal expiratory flow rate at 50% and 25% of the FVC ($\dot{V}_{max50}$, $\dot{V}_{max25}$), and maximal expiratory flow rate at 60% of total lung capacity (TLC) ($\dot{V}_{max60TLC}$) were measured. The ratio of residual volume (RV) to TLC was computed. Specific conductance of the airway was computed by dividing the reciprocal of resistance by the TGV. The plethysmography always preceded the maximal force expiratory maneuvers. A minimum of three plethysmographic measurements was performed, and the most reproducible and representative values were used for the calculations of TGV and airway resistance. The flow-volume curves were performed in triplicate, and the largest FVC was used to compute the flow rates. The RV was determined by subtracting the expiratory reserve volume from the TGV. The TLC was derived by adding the FVC and RV. All pulmonary function results were corrected to body temperature and pressure, saturated with water vapor.

Results of the pulmonary function tests were expressed as a percent change from baseline as well as a percent of predicted.[7-10] When expressed as a percent change from baseline, the results of pulmonary function measured at the same time after normal saline and aminophylline were analyzed for significant differences with the Wilcoxon signed rank test.[11] Results expressed as a percent of predicted were analyzed with a two-way analysis of variance and Dunnett's test for multiple comparisons[11] to determine if changes after either normal saline or aminophylline differed from the baseline pulmonary functions for that day.

Pharmacokinetics of theophylline were measured on the first study day. No subject was taking medication containing theophylline prior to the study, and all had abstained from foods and beverages containing xanthines for at least 48 hours prior to study. A single dose of aminophylline equivalent to 4.0 mg/kg of theophylline (anhydrous) was given at a constant rate by infusion pump for five minutes. Blood samples were obtained before injection and at 5, 10, 15, 20, 30, 40, 50, 60, 120, 180, 240, 360, and 480 minutes after the end of the injection. Serum theophylline levels were measured by high-pressure liquid chromatography using a modification of the method of Weddle and Mason.[12] Pharmacokinetic parameters (half-life, total clearance, and volume of distribution) were calculated from the best computer fit of the serum concentration-time curves obtained for each patient. The serum theophylline data were analyzed using MULTFIT, a nonlinear regression analysis program.[13] Without exception, the data from all subjects were best fitted by a bioexponential equation, corresponding to the well-established two-compartment model for theophylline distribution and elimination.

Blood drawn before the aminophylline infusion was also analyzed for γ-glutamyl transpeptidase and for transaminases (SGOT, SGPT) as indicators of hepatobiliary disease. γ-Glutamyl transpeptidase was determined by the method of Szasz,[14] whereas the method of Henry and associates[15] was used to assay the levels of SGOT and SGPT.

RESULTS

Significant decreases in airway obstruction after IV aminophylline were noted when the aminophylline response was compared with the saline response (Table 2) and also when the aminophylline response was compared with the baseline pulmonary functions before the infusion (Table 3). Compared with baseline, group mean values of TGV and RV decreased 24% to 37% ($P < .01$), whereas $\dot{V}_{max60TLC}$ increased from 35% at three hours ($P < .05$) to 64% at five hours ($P < .05$). In addition, aminophylline infusion increased specific conductance of the airway by 36% to 44% ($P < .02$ at one and three hours). The RV/TLC ratio decreased from 0.50 at baseline to 0.38 at three hours ($P < .01$). The TLC decreased from a mean of 122% of predicted at baseline to 102% of predicted at three and five hours after aminophylline infusion ($P < .01$).

An example of the type of changes in lung function found after administration of IV aminophylline is shown in Fig 1. The predicted flow-volume curve for patient 9 is plotted on an absolute lung-volume scale along with the curves at baseline and after IV aminophylline. Before aminophylline, the pattern of changes in pulmonary function in CF can be seen where TLC and RV are elevated, and the flow-volume curve is convex to the volume axis consistent with an obstructive lung disease. It can be seen that not only is the shape of the flow-volume curve abnormal, but flow at any absolute lung volume is markedly decreased. After aminophylline, the major change is a decrease in the obstruction manifest by a decrease in TGV and RV, an increase in vital capacity, and a variable decrease in the convexity of the flow-volume curve. Changes in pulmonary function such as this result in marked increases in flow rates at any absolute lung volume (Fig 1) with less marked but significant changes in flows related to the observed TLC at the time of each measurement. Flows related to vital capacity (eg, $\dot{V}_{max25}$) that do not take absolute lung volume into consideration will show no change or a small increase in flow.

Thoracic gas volume and RV, both expressed as a percent of predicted instead of percent change from baseline, are plotted in Fig 2 to illustrate

Table 1.—Profile of Patients Studied With Intravenous Aminophylline and Normal Saline

Patient No./ Age, yr/Sex	Height, cm	Weight, kg	NIH Score*	Allergy Profile: Positive† Skin Test	Allergy Profile: Allergic Rhinitis	Allergy Profile: Wheezing
1/15/F	161	43.5	64	2	+	—
2/10/F	144	31.9	86	3	+	—
3/18/F	158	41.0	92	12	—	—

the average degree of airway obstruction at baseline and the average reversibility. The RV was approximately 284% of predicted at baseline and had decreased to 177% of predicted at three hours, whereas TGV was 163% of predicted at baseline and fell to 117% of predicted at three hours (Table 3). These changes are significant ($P < .01$).

Although the mean increase in $\dot{V}_{max50}$ was 20% at five hours after IV aminophylline and the mean increase in vital capacity was 7.3% at three and five hours after the infusion, the improvement in these and the other pulmonary functions (airway resistance, peak expiratory flow rate) was less uniform and/or of less magnitude and therefore not statistically significant. On the other hand, all ten patients had at least a 13% decrease in TGV after the aminophylline infusion. After the normal saline infusion, only two children had a decrease in TGV, and the maximum decrease was only 4%. Again, this latter infusion was single-blind, and the patient did not know if he was receiving saline or aminophylline. All results for TGV are given in Table 4. The values of TGV had to be reproducible to be acceptable (ie, the three measurements at a given study time), and over 90% of the volumes given were reproducible to within ± 3%, with 50% of the volumes being exactly reproduced at the time of measurement.

The mean serum theophylline level at one hour was 5.8 μg/mL, with a range of 4.4 to 7.2 μg/mL, and at three hours the mean was 4.3 μg/mL, with a range of 3.0 to 6.3 μg/mL. Within this small, low range of serum theophylline levels, no correlation was found between serum drug level and the reversibility of the airway obstruction.

Table 5 is a listing of the individual half-lives, calculated from the elimination or β phase of the serum concentration-time curves. Also summarized in the table is the total clearance and volume of distribution for the subjects with CF. The individuals with abnormal results of liver function tests are indicated.

There was no correlation between the degree of improvement in lung function after IV aminophylline and the patient's age, number of positive skin tests, NIH score, or degree of pulmonary function abnormality at baseline.

COMMENT

Reversibility of the airways obstruction in patients with CF after bronchodilator therapy has been studied, but the published results and conclusions are conflicting.[1,16-25] These differences may be related to several factors. Isoproterenol hydrochloride has been the most frequently studied bronchodilator in patients with CF, but the dose, method of delivery, and

time of testing after delivery of medication have varied from one study to another.[17,19,20,22-25] In addition, only two previous studies of inhaled bronchodilators controlled the evaluation by repeating pulmonary functions using the same test conditions without a bronchodilator.[20,26] Two uncontrolled studies[23,25] found that maximal expiratory flows could decrease after isoproterenol inhalation in patients with CF, leading to the suggestion that isoproterenol might be causing the decreased flows by decreasing smooth-muscle tone of airways, thereby allowing greater collapse of airways during a forced expiration. Though this argument may be valid, the need for controlled studies of bronchodilator effect in CF is supported by the observations of Lifshitz and Denning[20] and of Larsen et al,[26] who showed that repeated pulmonary function maneuvers may cause decreased flows and increased gas trapping in patients with CF. This was again noted in this study, where flows tended to decrease while TGV and RV usually increased or became more abnormal in the control study (Table 2).

Several studies of bronchodilators in CF have evaluated pulmonary function parameters that are less sensitive indicators of the small airway disease than are those used in the present study.[17,19,20] From the work of Cooper and associates,[27] the most sensitive tests for detecting abnormalities in CF include RV/TLC ratio and $\dot{V}_{max60TLC}$. For both lung functions, absolute lung volumes must be known.

In order to overcome some of the problems of earlier studies, the present study used a controlled protocol where subjects were retested in a blind manner with IV saline alone. In addition, a dose of medication based on the weight of the patient was administered by the IV route to avoid possible problems caused by different rates and degrees of absorption of oral medicine. Furthermore, information from both a body plethysmograph and flow-volume curve were employed in evaluating responses so that we could assess changes in absolute lung volumes and flows related to these lung volumes. This latter aspect of our study may explain the difference between our results and those of Shapiro and co-workers, who found no consistent beneficial response to oral theophylline.[1] The larger postaminophylline increase in flow, when related to TLC noted in this study, and the lack of significant change in most flows related to vital capacity in both this study and the study of Shapiro and associates,[1] are explained by the simultaneous change in TGV and RV after aminophylline. It is only when absolute lung volumes are examined

*Based on normal values in Polgar and Promadhat.[7]

that a consistent beneficial effect of the aminophylline is noted.

The importance of examining patients with obstructive lung disease for changes in lung volumes has been pointed out by Woolcock and Read,[28] who noted that some patients clinically recovering from asthma will not show significant improvement in flows on a spirogram but will have marked decreases in TLC and RV, reflecting a decrease in the degree of hyperinflation. Their illustration of these changes, shown by placing the volume-time tracing (spirogram) on an absolute lung-volume scale, is similar to Fig 1, where flow-volume curves are examined on an absolute lung-volume scale. Benatar and Konig[29] have also employed maximal expiratory flow-volume curves on an absolute lung-volume axis to study the response of asthmatics to exercise and bronchodilators. They also noted that in some subjects, changes in RV and TLC developed without a change in the slope of the maximal expiratory flow-volume curve. They believed that lung-volume changes might reflect functional closure of some lung units, whereas changes in slope of the curve would reflect changes in the time constants in the lung. Based on this interpretation, the parallel shifts in the flow-volume curve with variable improvement in slope might mean that the major effect of this IV dose of aminophylline in these patients with CF was to decrease peripheral airway obstruction and thus decrease functional closure of some lung units. More detailed studies would be needed to address this point.

Recently, Ramsdell and Tisi[30] have reemphasized the importance of including measurements of static lung volumes in assessing pulmonary response to bronchodilators. In patients with obstructive lung disease who responded to isoproterenol inhalation, they found that 41% exhibited bronchodilation by significantly improving static lung volumes without improving expiratory flows. In contrast, 44% had significant changes in expiratory flow but not in lung volume, whereas 15% showed improvement in both flows and volumes. In general, the subjects showing only volume changes had more severe airway obstruction and hyperinflation at baseline. They pointed out that if a response had been assessed only in terms of increased expiratory flows, improvement would have been overlooked in several of the patients. Based on the changes in lung function noted in this study, observations for changes in lung volumes in patients with CF may be very important in assessing response to bronchodilators.

Nine of the ten patients studied had at least one positive skin test to common inhaled aeroallergens. A high incidence of positive skin tests in CF has been reported.[3,31,32] Warner et al[32] have suggested that the atopy may be secondary to impaired handling of antigen at a mucosal surface. In our population of children with CF, we would expect over 60% to have at least one positive skin test to common aeroallergens.[3] We found no correlation between the number of positive skin tests and the reversibility of the airway obstruction. Further support for the nonspecific nature of positive skin tests in CF was recently reported by Mellis and Levison, who found that positive response to inhaled histamine in patients with CF correlated with abnormal pulmonary functions but not with positive skin tests.[33] Another study from the same laboratory came to the same conclusion after studying methacholine responses in patients with CF.[34] In addition, Nelson et al have recently interpreted the increased skin reactivity in CF as representing increased sensitization from allergen contact with a more permeable, damaged respiratory epithelium.[35] Therefore, the fact that most subjects tested had positive skin tests does not necessarily mean that their airways are more likely to respond to bronchodilators. However, more subjects with no skin-test reactivity would have to be studied to address that question.

The serum theophylline levels that were measured one and three hours after the IV infusion were lower than the commonly recommended therapeutic levels of 10 to 20 μg/mL.[36] However, as previously reported by Maselli and co-workers, therapeutic effects of theophylline can be seen with low serum levels in childhood asthma.[37] It remains to be determined if higher plasma concentrations in patients with CF would further decrease pulmonary function abnormalities.

The pharmacokinetic analysis provided both individual and mean values for theophylline half-lives, total clearances, and volume of distribution (Table 5). These values can be compared with similar published results for children with asthma. Ellis et al[38] found that 30 asthmatic children of similar age to those we studied had a half-life value of 3.69 ± 1.13 hours, with a range of 1.42 to 7.85 hours. This mean value is shorter than the half-life of 4.66 ± 1.10 hours for the patients with CF, but the range for our group of patients is again wide (3.08 to 6.15 hours), reflecting large interindividual variation. Total clearances were similar in both studies (91 mL/hr/kg in CF vs 87 mL/hr/kg in asthma), but again much interindividual variation was noted. The volume of distribution, however, for children with CF

Table 5.—Pharmacokinetics of Theophylline in Patients With Cystic Fibrosis

Patient	Half-life, hr	Total Clearance, mL/hr/kg	Volume of Distribution, mL/kg
1	3.08	116	517
2	4.76	78	532
3*	5.82	64	539
4	5.15	83	614

*Patients with abnormal liver function tests results.

(574 ± 66 mL/kg) was significantly larger ($P < .01$) than the value reported for children with asthma (422 ± 64 mL/kg). A diminished volume of distribution for theophylline has been previously attributed to obesity.[39] It is therefore reasonable to assume that the decreased adipose tissue in patients with CF could result in the larger volume of distribution per unit of body weight.

Because theophylline is metabolized in the liver, we wanted to determine if the pharmacokinetic variability was related to liver function. Kattwinkel and co-workers[40] found abnormal results of liver function tests in 15 of 40 (37.5%) patients with CF. We found evidence of hepatic dysfunction in four of our ten subjects based on abnormal serum elevations for age of γ-glutamyl transpeptidase, SGOT, and/or SGPT. The patients with abnormal test results are noted in Table 5, and as can be seen, those subjects with serologic abnormalities generally had the longest half-lives and the lowest clearances for this drug. This high incidence of hepatic dysfunction and interindividual variation in kinetics emphasize the point that theophylline dosage regimens in children with CF must be individualized and carefully monitored if this drug is used clinically.

Georgia Wheeler helped in the preparation of the Manuscript and Gary Zerbe, PhD, helped in the statistical analysis.

Pneumatosis Intestinalis

Its Occurrence in the Immunologically Compromised Child

Paul K. Kleinman, MD; Paula W. Brill, MD; Patricia Winchester, MD

• Four immunologically compromised children, two with acute lymphoblastic leukemia who received immunosuppressive therapy, one with X-linked agammaglobulinemia, and one with chronic granulomatous disease of childhood, displayed both the pulmonary and gastrointestinal mechanisms that led to pneumatosis intestinalis. Consideration of both the basic disease and the immediate clinical circumstances that surround the development of intramural air are helpful in the determination of the significance of pneumatosis intestinalis in individual patients.

(*Am J Dis Child* 134:1149-1151, 1980)

Necrotizing enterocolitis is the most frequent cause of pneumatosis intestinalis in the neonate.[1] In the older child, this condition is uncommon and usually occurs in association with a serious underlying disease. The presence of intramural gas may reflect structural alterations in the bowel wall. It may also arise by transdiaphragmatic dissection of extra-alveolar air in patients with lung disease.[2-7] In patients with congenital or acquired immunodeficiency, localization of the source of the intramural gas may be difficult. Thus, an understanding of potential causes and mechanisms that give rise to intramural intestinal air aids in assessment of the significance of pneumatosis intestinalis in the immunologically compromised patient.

REPORT OF CASES

Case 1.—An 11-year-old boy, with X-linked agammaglobulinemia and a history of recurrent pneumonia, showed pneumatosis intestinalis and pneumomediastinum on roentgenograms taken during evaluation of an acute respiratory infection (Fig 1). There were no abdominal complaints. Resolution of the abnormal air collections was documented on follow-up roentgenograms three weeks later.

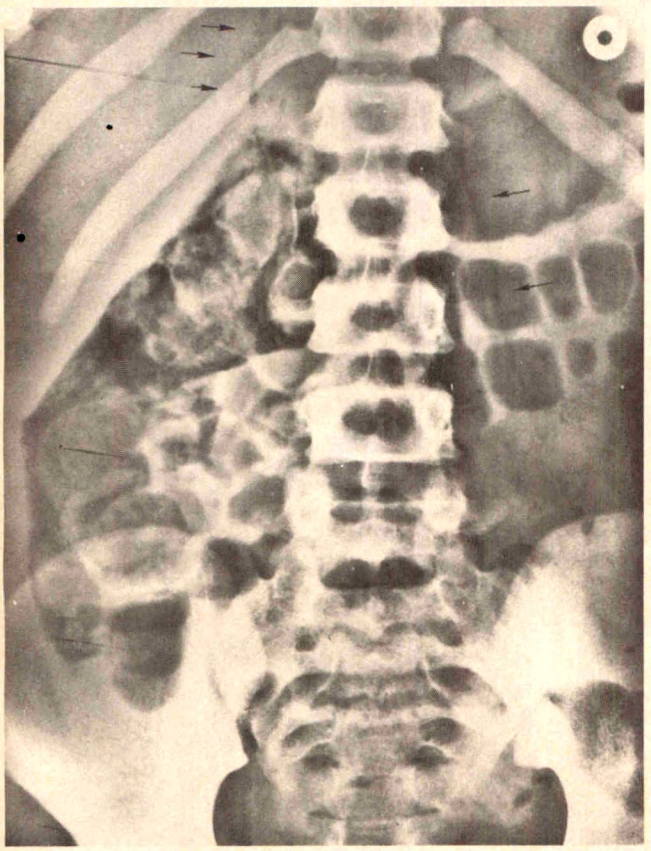
Case 2.—A 14-year-old girl with acute lymphoblastic leukemia in relapse had cavitary lung lesions, probably due to *Aspergillus*. She received prednisone and cytotoxic agents for the leukemic relapse and amphotericin B for the *Aspergillus* infection. The lung lesions diminished, but some were still present when right upper quadrant pain and abdominal distention developed. Pneumatosis intestinalis as well as retroperitoneal air were demonstrated on a roentgenogram of the abdomen (Fig 2). Symptoms abated within two days, and the pneumatosis intestinalis and retroperitoneal and mediastinal air resolved in two weeks.

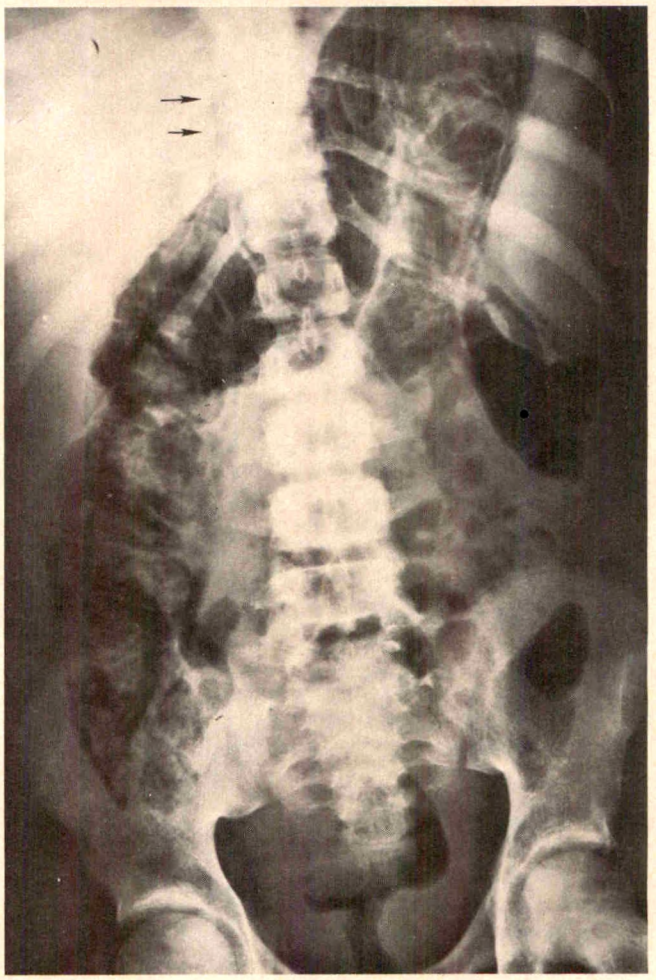
Case 3.—A 5-year-old boy with chronic granulomatous disease had acute abdominal distention and watery diarrhea during the course of treatment for staphylococcal pneumonia. An abdominal roentgenogram demonstrated pneumatosis intestinalis (Fig 3). *Salmonella enteritidis*, type infantis, grew from cultures of stool, ascitic fluid, and blood. Chest roentgenograms showed no evidence of extra-alveolar air. Diarrhea and distention resolved with the institution of therapy with gentamicin sulfate and ampicillin sodium. The pneumatosis intestinalis was not visible eight days after its initial identification.

Case 4.—A 14-month-old boy (previously mentioned by Meyers et al[6]) with acute lymphoblastic leukemia in remission was admitted to the hospital with fever and dehydration after five days of severe, watery diarrhea. The abdomen was soft and cultures of stool initially grew normal flora. Methicillin sodium, gentamicin, and ampicillin were given because of the possibility of a rectal abscess. Diarrhea continued, and on three occasions enteropathogenic *Escherichia coli* were recovered from the stool. Eleven days after admission, an abdominal roentgenogram showed extensive pneumatosis intestinalis that involved the descending colon and rectosigmoid. The pneumatosis gradually decreased with the institution of therapy with colistin sulfate. Diarrhea and fever resolved, and subsequent cultures of stool were negative for pathogens.

COMMENT

Pneumatosis intestinalis may arise by dissection of intraluminal gas into





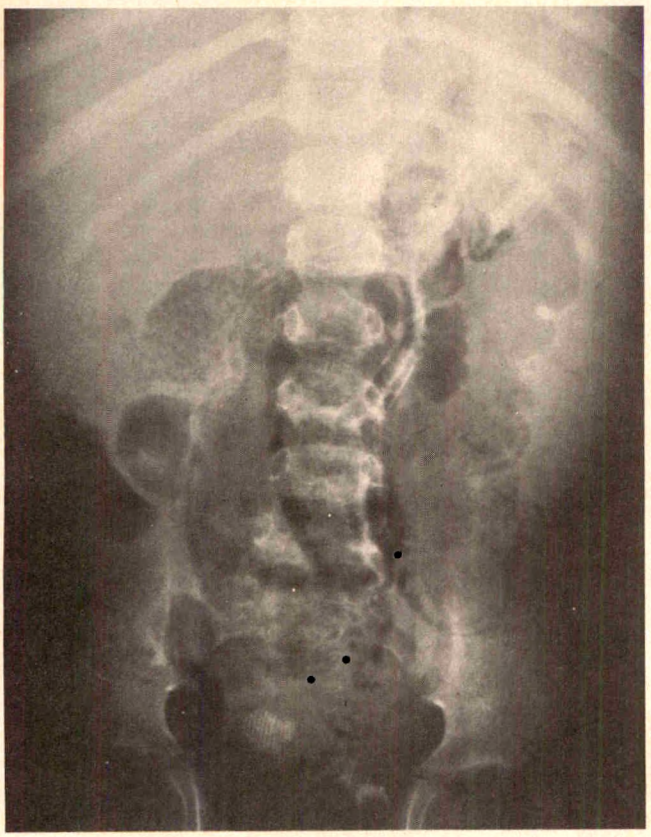


Fig 1 (top, left).—Case 1. Extensive pneumatosis intestinalis of right colon: retroperitoneal air is present in right suprarenal region and along left psoas margin (arrows).

Fig 2 (top, right).—Case 2. Extensive pneumatosis throughout ascending and transverse colon. Linear collections extend into interhaustral folds. Retroperitoneal air outlines right diaphragmatic crus (arrows).

Fig 3 (bottom).—Case 3. Supine abdominal roentgenogram on 5-year-old boy with chronic granulomatous disease and *Salmonella* enterocolitis. Linear pneumatosis intestinalis involves colon in midabdomen and left abdomen. Intramural air extends into interhaustral folds of lateral margin of descending colon. No evidence of retroperitoneal air is present.

the bowel wall secondary to mechanical or ischemic mucosal injury. Enteric organisms may contribute to this gaseous accumulation. This mechanism explains its development in neonatal necrotizing enterocolitis,[1] as well as in inflammatory or ischemic bowel disease in older children.[8-10] It may also occur secondary to structural alterations of the bowel wall without actual ischemic injury, providing access of intraluminal gas to the submucosa. This mechanism has been proposed for the development of pneumatosis intestinalis in patients with leukemia who have depleted lymphoid tissue secondary to immunosuppressive therapy.[11] Pneumatosis intestinalis has also been noted in patients with collagen vascular disease.[12] Structural alterations without ischemia may explain its occurrence in these patients[13]; however, compromise of splanchnic blood flow secondary to vasculitis also plays a significant role in some cases.[8]

Pneumatosis intestinalis may also arise from pulmonary air leakage. Air arising from alveolar rupture with dissection along the perivascular planes to the mediastinum can extend transdiaphragmatically, ultimately to an intramural intestinal location.[5] This transdiaphragmatic extension can occur posteriorly through the aortic hiatus of the diaphragm, as well as anteriorly through the Morgagni's foramina.[14] This mechanism likely explains its occurrence in children with cystic fibrosis and other forms of pulmonary disease that lead to air-block phenomena.[2-7]

The presence of pulmonary disease and the lack of intra-abdominal signs and symptoms suggest that the chest was the source of the pneumatosis intestinalis in cases 1 and 2. In case 3, with both staphylococcal pneumonia and *Salmonella* enterocolitis, the source could have been either pulmonary or intestinal. Case 4 is especially interesting as this patient had pneumatosis intestinalis in the face of severe enterocolitis due to enteropathogenic *E coli*. Though structural alterations of the bowel wall due to immunosuppressive therapy may have predisposed to the development of the intramural intestinal air, the infectious process probably played a significant role.

The significance of pneumatosis intestinalis in any given case is best understood by a consideration of the ways in which the underlying disease and its therapy may alter the bowel wall and by an awareness that superimposed disease in either the chest or abdomen may be the source of intramural gas.

Necrotizing Enterocolitis

Epidemic Following an Outbreak of *Enterobacter cloacae* Type 3305573 in a Neonatal Intensive Care Unit

Julie Powell, MD; Michel A. Bureau, MD, FRCP(C); Claude Paré, MD;
Marie-Lyse Gaildry, MD; Diane Cabana, MD; Heidi Patriquin, MD, FRCP(C)

• Twelve cases of necrotizing enterocolitis (NEC) occurred within three weeks in a neonatal intensive care unit (NICU) with 325 annual admissions. *Enterobacter cloacae* type 3305573 was found in stool and/or blood cultures from affected babies prior to the onset of the disease. This bacterium could not be grown in cultures from infants in the same NICU six weeks later. A causal relationship between *E cloacae* and the epidemic of NEC is suggested.

(*Am J Dis Child* 134:1152-1154, 1980)

The precise etiology and pathophysiology of necrotizing enterocolitis (NEC) remain unclear, but several observations have supported the role of an infectious agent in its pathogenesis. A few epidemics of NEC have been reported[1-7] and these have been associated with various enteropathogenic bacteria such as *Escherichia coli*,[2] *Klebsiella pneumoniae*,[3] *Salmonella*,[4] and *Clostridium butyricum*.[5] Three other reports of epidemics of NEC failed to incriminate a particular pathogen.[1,6,7] Recently, it has been suggested that recognition of NEC as a potentially epidemic disease and implementation of infection control measures can decrease the incidence of NEC.[7] We report an epidemic of NEC in our neonatal intensive care unit (NICU) and its association with a nosocomial infection with *E cloacae* type 3305573.

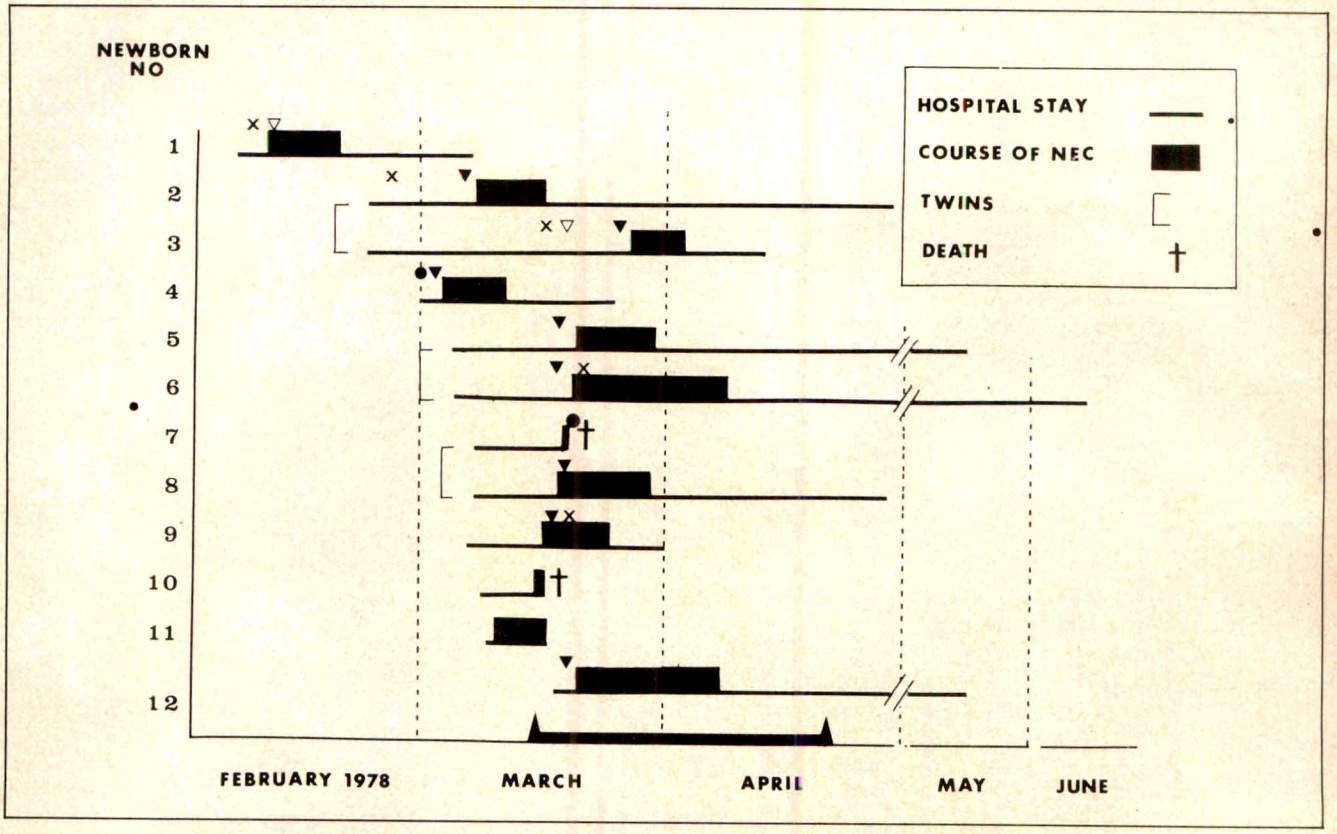
From the Departments of Pediatrics (Drs Powell, Bureau, Paré, Gaildry, and Cabana) and Radiology (Dr Patriquin), Faculté de Médecine, Université de Sherbrooke, Québec.

Reprint requests to Département de Pédiatrie, Faculté de Médecine, Sherbrooke, Québec, Canada J1H 5N4 (Dr Bureau).

DESCRIPTION OF EPIDEMICS

Twelve cases of NEC occurred at the NICU of the Centre Hospitalier Universitaire de Sherbrooke during February and March 1978, and 11 of these occurred within the 18-day period from March 3 to 21 (Fig 1). This represents 32% of all admissions to our NICU for that period (11/34). In the two months preceding and in the two months following the epidemic of NEC, there were no other cases of NEC in the unit. There were only three patients with NEC in 1977 and six (excluding the epidemic) in 1978.

All of the babies involved in the epidemic of NEC were premature (mean gestational age, 33.3 weeks; mean weight, 1,667 g), either born at our hospital (4/12) or referred because of prematurity and/or respiratory distress syndrome (8/12). All of these had the classic[8] clinical and radiological features of NEC. Clinical signs were as follows: abdominal distention (ten patients); feeding intolerance (eight); gastrointestinal (GI) tract bleeding (eight); diarrhea (three); hypotension (two); and apnea (five). Radiological signs were as follows: intestinal distention (local or generalized) (12); pneumatosis intestinalis (ten); pneumoperitoneum (two); and portal venous gas (one). The mean age at which these were first observed was 10.3 days. Their predisposing factors, as reported by others,[1,2] included prematurity, (12/12); hyaline membrane disease (11/12); perinatal shock (10/12); and placement of an arterial umbilical catheter (9/12). Eight of the 12 patients had been fed cow's milk formula (Similac), and four, human milk. After the diagnosis of probable or definite NEC was made for each patient, the treatment consisted of total parenteral nutrition and parenteral antibiotic therapy (ampicillin trihydrate, 100 mg/kg/day, gentamicin sulfate, 5 mg/kg/day), bicarbonate infusion, and fresh blood transfusions when blood hemoglobin concentration was 10 g/dL or below. Surgery was necessary in two patients who had bowel perforation. One of these died shortly after surgery; the



Schematic presentation of temporal relationship among 12 patients with necrotizing enterocolitis (NEC). Timing of positive initial stool culture for *Enterobacter cloacae* type 3305573 is given by closed triangles; negative results, open triangles; circles indicate positive blood cultures; X, recovery of *E cloacae* from various sites of culture (trachea, pharynx, etc); heavy bar on abscissa, period of special infection control measures.

second (a fulminant case) died before operation could be performed. The other ten newborns recovered from their NEC without sequelae.

With the first four patients, only "isolette isolation" was adopted, and nurses were advised to observe careful handwashing technique. However, on March 16, the epidemic of NEC was recognized and additional prophylactic measures were adopted; these included confinement of all NEC patients to one room and of contacts to another room, and the placement of all new admissions in a third room. The contacts were patients who had been cared for by the same nurse or who were in the same room as the four patients with NEC. All patients were in isolettes, and their nurses were required to wear gowns and gloves. Consequently, in eight of the 18 contacts, obvious NEC developed, whereas the other ten contacts remained asymptomatic.

Our intermediate and intensive care unit consists of two rooms with a total bed capacity of 14 patients. When needed (as during the epidemic), a third room can be arranged to provide intensive care therapy. The nursing personnel are confined to one room, and within each room a nurse is responsible for two intensive care patients or three intermediate care newborns. However, during lunch hours the same nurse may provide care to other newborns within each room.

BACTERIOLOGIC FINDINGS

A search for a bacterial etiology of the enterocolitis began on March 16 by examination of stool and blood cultures from all four patients with NEC and stool cultures from all contacts. For those patients in whom signs of NEC developed later on, stool and blood cultures were repeated at the first sign of NEC, usually before the time of definite diagnosis. Unfortunately, a search for the source of the epidemic among nurses and house staff was not carried on.

Enterobacter cloacae type 3305573 was recovered as pure growth on the stool cultures from eight newborns with NEC (seven of these repeatedly); these cultures were positive early in the course of the disease or even before the appearance of the full clinical picture. The same *E cloacae* was also recovered from the blood cultures of two patients and at the postmortem examination of one. Thus, nine of the ten patients from whom adequate cultures were taken were infected with the same *E cloacae* in the early phase of their disease. A test for viruses was negative on the stool culture and at the electron microscopic examination of stools from four patients.

Among the initial 18 contacts identified on March 16, eight subsequently acquired a definite NEC; of these, six patients showed pure growth of *E cloacae* in their stool cultures, whereas two others (patients 7 and 10) died before adequate cultures were obtained. Among other contacts, four (4/10) had the same *E cloacae* in their stools but failed to show pure growth; *E cloacae* was mixed with two other enterobacteria (*Esch coli, Klebsiella*

and/or *Proteus mirabilis*). These patients were considered colonized but not infected; they had no sign of NEC, and aside from isolation, no specific therapy was required. These contacts who did not have NEC were not different from subjects with NEC in regard to gestational age (34.3 weeks), birth weight (1,795 g), early clinical course and incidence of early intravenous antibiotic therapy, umbilical catheter placement, and human-milk feeding.

After the epidemic period (the first week of May), all 15 patients in the NICU (12 new admissions and three patients of the epidemic) had a stool culture taken to ascertain the absence of endemic infection with *E cloacae* type 3305573 in the unit. All cultures were negative for *E cloacae*, but the usual mixed flora were found in 12 premature infants (*Esch coli*, *P mirabilis*,and *Serratia marcescens*) and no pathogens were found in the remaining three.

COMMENT

The clinical, radiological, and pathological features of NEC in the patients of this epidemic are similar to those reported in epidemics associated with other bacteria[2-5] or without known pathogens.[1,6] The role of *E cloacae* type 3305573 is not clear in this epidemic of NEC, but some arguments would favor a GI tract infection as the initial event in the pathogenesis of this disease in our predisposed population of premature newborns. First, the time course of events suggests an infectious epidemic. The first patient proven to have the incriminated *E cloacae* along with NEC during January might have been the source of the dissemination of the bacteria since only isolette isolation was recommended. Then, two weeks later, a cluster of NEC cases occurred, presumably following dissemination of the infectious agent to other newborns. A second argument relies on the type and the timing of the pure growth of *E cloacae* type 3305573 in the stools of patients with NEC. Eight of nine patients from whom adequate stool cultures were taken showed positive cultures very early in the course of NEC. Moreover, in six patients (2, 3, 4, 5, 6, and 12) the stool specimens showed pure growth of *E cloacae* before we could make a clinical and/or radiological diagnosis. A third argument is related to the pathogenicity of this bacterium, which was capable of inducing plurisystemic disease in our premature patients as demonstrated by septicemia in two patients and by diffuse infection at postmortem examination. Finally, as reported extensively by others in instances of nonepidemic NEC,[9] no clinical differences could be found in our patients in whom NEC developed and those in whom it did not. The only difference identified was the presence of *E cloacae* type 3305573.

Whether the enteric infection identified in our patients early in the course of NEC was an opportunistic infection occurring on a damaged intestinal mucosa remains unknown, but it appears likely that *E cloacae* type 3305573 was involved as an initial event in the development of NEC. This is consistent with other epidemics of NEC, particularly those occurring during a nosocomial infection with *C butyricum*,[5] *Salmonella*,[4] *Esch coli*,[2] and probably with *Klebsiella*.[3] All of these epidemics, as well as ours, were associated with an outbreak of a nosocomial infection involving bacteria that were proven not to be endemic in each of the NICUs, and all epidemics ceased with implementation of infection control measures. Reports of three other clusters of NEC failed, however, to identify a specific bacterium in association with the disease.[1,6,7] Additional reports of epidemiological data on clusters of NEC are needed to confirm the impression that some nosocomial infections can induce an epidemic of NEC in a predisposed population.

Radiological Case of the Month

Chakib Bennani-Smires, MD, Jocyline Medina, MD (*Contributors*); Lionel W. Young, MD (*Section Editor*)

A 3,200-g male infant was delivered by cesarean section because of fetal distress after an uneventful 38-week gestation. On the second day of life, fever and diarrhea developed. At 2 weeks of age, because of his failure to tolerate oral feedings, persistent diarrhea, and dehydration, total parenteral hyperalimentation therapy was started. A complete blood cell count showed a hypochromic, normocytic anemia. Results of a stool examination, an upper gastrointestinal series, and barium enema examinations were normal. A biopsy of the small bowel showed flattening of the mucosa consistent with chronic intractable diarrhea. By 5 months of age, he weighed 5,100 g and was pale but alert, nourished almost continuously by parenteral hyperalimentation. Diarrhea was persistent and without a definite cause. On roentgenographic examination of the chest, subperiosteal new bone of the diaphyses of the humeri was noted, and a roentgenogram of the lower limbs was obtained (Fig 1). Although hypochromic anemia persisted, serum calcium and phosphorus levels were normal. A follow-up roentgenogram was obtained one month later (Fig 2).

Figure 1.

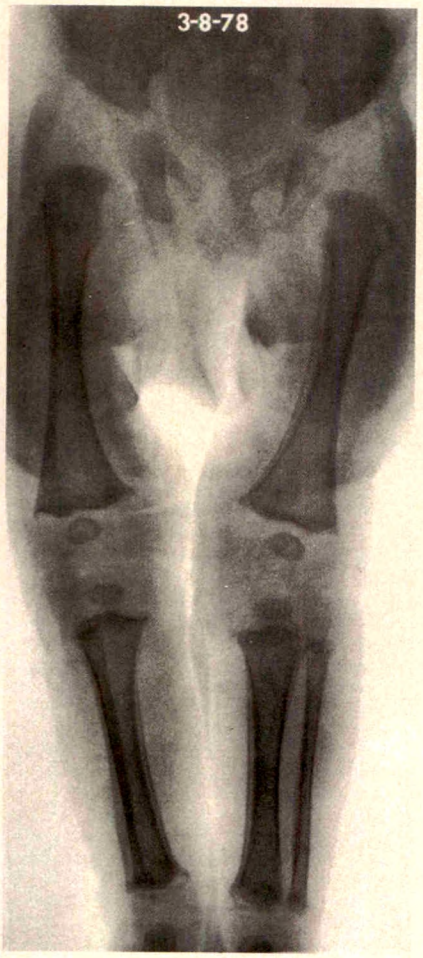

Figure 2.

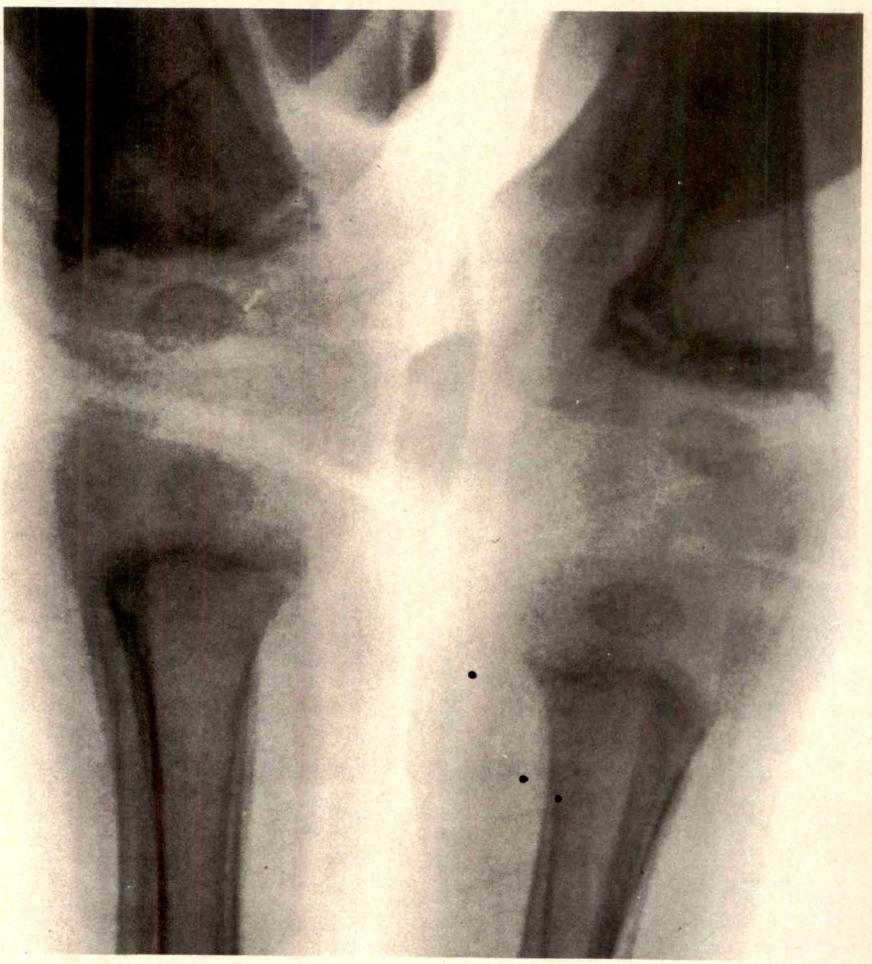

Infantile Nutritional Copper Deficiency

Fig 1.—Anteroposterior view of lower limbs; marked osteoporosis and subperiosteal new bone are present in long bones and ilia. Metaphyses have wavy and irregular outline. Distal femoral and tibial metaphyseal infractions are present. Note bucket-handle deformities of distal metaphyses of tibiae.

Fig 2.—One month after initiation of copper therapy, subperiosteal new bone is again apparent, and new bone healing of metaphyseal infractions is evident.

Fig 3.—Subperiosteal new bone formation along long-bone shafts is less apparent (remodeling). Metaphyseal infractions are completely healed, and line of residual sclerosis in each metaphysis is present.

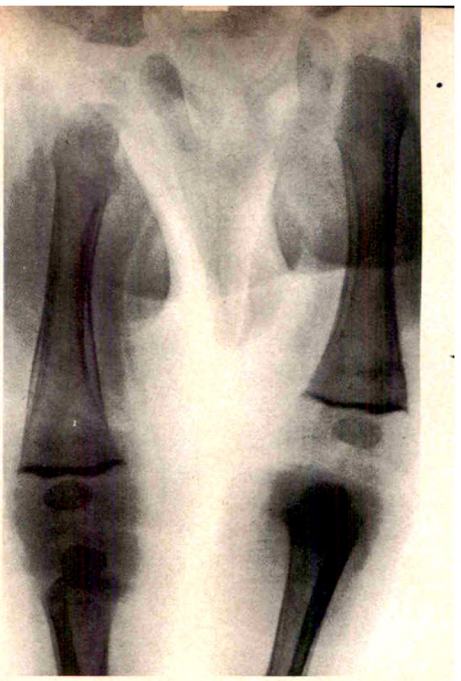

Figure 3.

Metaphyseal infractions of limb bones and subperiosteal new bone formation might occur in child abuse, but usually not bilaterally and symmetrically; neither would this be likely in an infant hospitalized since birth. Rickets would be unlikely because the blood levels of calcium and phosphorus were normal. Moreover, vitamin D in daily requirement doses was regularly given to our patient. Scurvy might be considered, but daily requirement levels of ascorbic acid were included in the parenteral feedings, and the roentgenographic changes are not typical for scurvy. A luetic origin is excluded because the serologic tests for syphilis in both parents were negative.

Corresponding long-bone roentgenographic changes were also present in the upper limbs, there being similar metaphyseal change in the proximal humeral metaphyses, although the distal metaphyses of the ulnae and radii appeared normal. The ribs showed rachitic-like cupping and splaying of their sternal ends.

Copper deficiency is especially consistent with the findings and symptoms in this infant who had received total parenteral nutrition since birth. Moreover, the serum level of ceruloplasmin was 0.6 mg/dL (normal, 17 to 28 mg/dL). The serum copper level was 7 μg/dL (normal, 60 to 190 μg/dL). After 21 days of copper therapy, the serum ceruloplasmin level was 14.5 mg/dL and the serum copper level was 71 μg/dL. Three months later, roentgenographic examination of the limbs showed conspicuous diaphyseal subperiosteal new bone remodeling and remodeling of the involved metaphyses, highlighted by a residual line of metaphyseal sclerosis (Fig 3).

Nutritional copper deficiency is rare. Usually the full-term infant has large reserves of copper in his liver. Case reports of infantile copper deficiency have been made in malnourished infants with chronic intestinal malabsorption,[1] in very small infants with pronounced liver damage,[2-4] and in infants and adults receiving prolonged total parenteral nutrition.[5,6] Normally, copper stores in the infant are sufficient for the first six months of life. The peak incidence of deficiency is at about 8 months of age.

The most important features of nutritional copper deficiency in infants are as follows: (1) the presence of a sideroblastic anemia with vacuolation of erythroid and myeloid bone marrow cells and iron deposition in the vacuoles and in some mitochondria[2]; (2) the coexistence of neutropenia, especially segmentopenia; (3) morphological findings of depigmentation of skin and hair and distended blood vessels due to changes in the elastin of the vessel walls; and (4) functional CNS deficits, including hypotonia and psychomotor retardation. The roentgenographic findings in nutritional copper deficiency are (1) long-bone osteoporosis, (2) cupping, flaring, and fractures of the metaphyses, (3) periosteal new bone, and (4) calcifications of the soft tissue.

The anemia is resistant to iron therapy in the absence of copper. The biochemical basis for the long-bone changes is the formation of an abnormal collagen with reduced structural integrity due to a decrease in the cross-links that normally form aldehyde groups and to a copper-dependent reaction along the polypeptide chains.[2,5]

Although this patient showed healing of the skeletal lesions, verifying the effectiveness of copper replacement therapy, the infant died at 9 months of age of severe sepsis and metabolic acidosis.

Review

Vitamin E and the Neonate

Richard A. Ehrenkranz, MD

In 1922, Evans and Bishop[1] demonstrated the existence of a fat-soluble dietary factor that was required for reproduction in rats. Animals deficient in this factor, which was designated vitamin E,[2] ovulated and conceived normally, but fetal death and resorption occurred at some time during gestation.[3] Evans and his associates[4] isolated the vitamin from wheat germ oil in 1936 and proposed the name "α-tocopherol" from the Greek *tokos*, a noun meaning childbirth, and *phero*, a verb meaning to bear. The suffix, *-ol*, was added to indicate that the substance was an alcohol. Although eight different tocopherols with vitamin E activity have been shown to occur naturally, α-tocopherol (Fig 1) is considered to be the most important, since it possesses the greatest biological activity and comprises about 90% of the total tocopherols present in animal tissues.[5] The standard unit of vitamin E activity is DL-α-tocopheryl acetate, 1 mg being equal to 1 IU. Table 1 compares the activity of different α-tocopherol compounds.[5]

Vitamin E has been extensively investigated during the past several decades. The signs and symptoms of vitamin E deficiency in animals have been thoroughly reviewed[5,6] and include effects on the reproductive, muscular, cardiovascular, and hematopoietic systems. Although clinical correlations to these pathologic manifestations have been sought, vitamin E deficiency does not readily occur in adult humans owing to the resistance of their tissue stores to depletion and to its wide distribution in foods.[7,8] However, human vitamin E deficiency has been described in association with malabsorption syndromes of various origins and in neonates, especially premature neonates.[5-7] After discussing the mode of action of vitamin E, this communication will review vitamin E status in the perinatal period and the factors underlying the development of vitamin E-deficiency anemia in the neonate. The recommended dietary vitamin E requirements for the neonate will then be discussed with respect to the interrelationship of vitamin E, polyunsaturated fatty acids (PUFAs), and iron; and finally, the therapeutic importance of vitamin E in the neonatal period will be reviewed.

MECHANISM OF VITAMIN E ACTION

The precise mode of action of vitamin E has not been demonstrated; however, it is thought to function as a lipid antioxidant, diminishing the peroxidation of polyunsaturated lipids by scavenging free radicals generated during the univalent reduction of molecular oxygen[9] and during the normal activity of oxidative enzymes.[10] Lipid peroxidation is the oxidative deterioration of polyunsaturated lipids.[11,12] It involves the reaction of highly reactive intermediates of oxidative metabolism and lipid and results in the formation of semistable lipid peroxides.[11,12] Kinetic experiments by Gruger and Tappel[13] suggest that vitamin E inhibits peroxidation of membrane lipid by acting as a reducing agent and providing protons directly to free radicals to form water. In addition, vitamin E may interrupt the chain reactions associated with lipid peroxidation by scavenging lipid peroxides.[11,12] Scavenging reactions with methyl[14] and alkyl[15] radicals have been demonstrated.

Lucy[16] has also proposed that vitamin E is an important structural component of biological membranes, interacting with membrane phospholipids such that membranes containing relatively high levels of PUFAs would also require large amounts of vitamin E to ensure structural stability. His studies[16] with molecular models suggest that the methyl side groups of the vitamin E core may be linked to membrane phospholipids by fitting within the double-bond structure of linoleic, linolenic, and arachidonic acid residues. Inhibition of lipid peroxidation by vitamin E has been shown to correlate with its binding to complexes of unsaturated lipids and membrane structural proteins,[17] providing evidence that membrane-associated vitamin E accounted for the antioxidant influence.

The mechanisms of vitamin E action just discussed are based on in

D-α-tocopheryl acid succinate	0.83

vitro studies. However, during the past several years, a number of investigators have reported in vivo evidence of vitamin E's antioxidant influence. Administration of carbon tetrachloride to mice[18] and rats[19] induced in vivo lipid peroxidation that was accompanied by the expiration of ethane, which could be diminished by pretreatment with vitamin E. Hafeman and Hoekstra[20] demonstrated that spontaneous in vivo lipid peroxidation, monitored by analysis of expired air for the presence of ethane, occurred in vitamin E- and selenium-deficient rats. Dillard and his colleagues have also correlated pentane expiration with in vivo lipid peroxidation in vitamin E-deficient rats[21] and in rats receiving various levels of dietary vitamin E, selenium, and PUFAs.[22] Figure 2 illustrates the reactions in which ethane evolves during the decomposition of linolenate hydroperoxide and pentane during the decomposition of linoleate or arachidonate hydroperoxide.[23] Pentane expiration was found to be directly related to the linoleic acid content of the diet[22] and inversely related to the dietary vitamin E concentration.[22-24] Dietary selenium decreased pentane production in vitamin E-deficient rats receiving a diet high in linoleic acid, but that effect was related to the activity of blood glutathione peroxidase, a selenoenzyme, which did not increase as the dietary selenium content was raised above the recommended level.[22]

Although Tappel[11,12] has stated that vitamin E is "the major biological antioxidant," endogenous antioxidant protection is provided by a number of other dietary components, including selenium, sulfur amino acids, and vitamin C.[11,12] Optimum tissue levels of these biologic antioxidants should result in adequate protection against oxidant and lipid peroxidative damage. The interrelationships between these substances, particularly selenium and vitamin E,[26] is complex and will not be discussed in any further detail in this report.

VITAMIN E STATUS IN THE PERINATAL PERIOD

Dju et al[26] measured the total body stores of vitamin E in human fetuses and neonates who died within nine days of birth. Twenty-two fetuses between 2 and 6 months of gestational age had an average of 3.1 mg of total tocopherols per kilogram of body weight compared with 5.6 mg of total tocopherols per kilogram of body weight in a 3,570-g full-term stillborn infant and an estimated 70 mg/kg of body weight in an adult. A linear relationship between total lipid or body weight and total tocopherol content of the fetuses was noted. Since adipose tissue was found to contain the greatest concentrations of tocopherols and since the amount of adipose tissue increases from less than 1% of body weight during the first two trimesters to approximately 16% of body weight at term,[27] Dju et al[26] stated that tocopherol body stores were low in the fetus and only slightly higher in premature and term infants.

A number of studies[28-35] have determined blood vitamin E levels in newborn infants and their mothers and have consistently noted that maternal levels at delivery or in the immediate postpartum period were higher than neonatal levels. Mean maternal levels ranged from 0.92 to 2.53 mg/dL compared with mean levels ranging from 0.24 to 0.61 mg/dL in the newborn (Table 2), with no significant difference in the vitamin E levels of premature and term infants.[29-31,35,36] Since the normal adult blood level of vitamin E is 1.05 mg/dL with a 2-SD range of 0.5 to 1.6 mg/dL,[7] these findings suggest that vitamin E levels are generally elevated during pregnancy and that the neonate may be considered chemically deficient in vitamin E. In addition, these data are consistent with the low fetal and neonatal body stores of vitamin E noted above.[26] Since the ratio of maternal to neonatal blood levels ranged from 2.6 to 5.7:1 (Table 2), the data also indicate that transfer of vitamin E from the mother to the fetus is limited. Leonard et al[31] noted a significant linear correlation between maternal blood levels of vitamin E and corresponding cord blood levels, finding that infants born to mothers with vitamin E levels less than 0.7 mg/dL had significantly lower vitamin E levels than infants born to mothers with vitamin E levels greater than 0.7 mg/dL. Mino and Nishino[32] confirmed that correlation and reported that, although supplementary vitamin E administration to women during the weeks prior to their delivery raised both the maternal and cord blood levels of vitamin E significantly, the levels in cord blood increased an average of only 0.11 mg/dL compared with an increase of 0.82 mg/dL in maternal blood (Table 2).

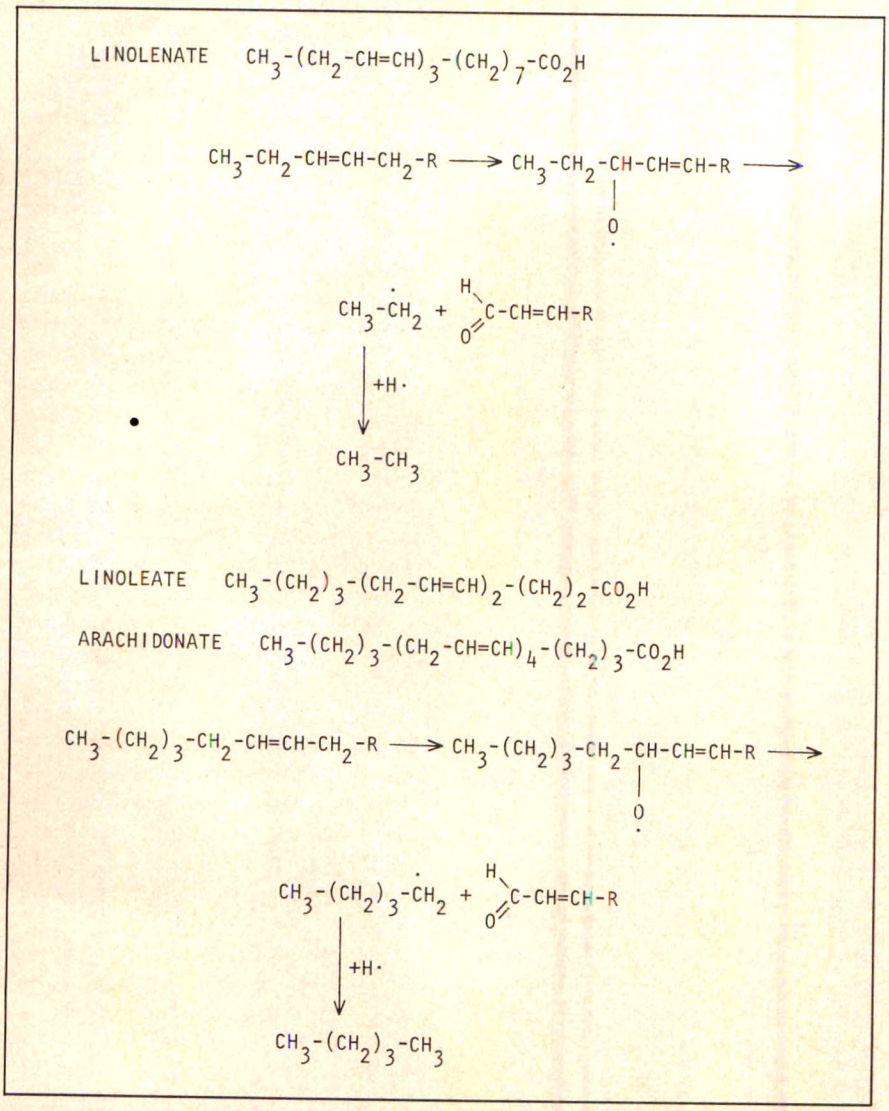

Fig 2.—Evolution of hydrocarbon gases during lipid peroxidation. Ethane evolves from decomposition of alkoxy radical of linolenate and pentane from alkoxy radical of linoleate and arachidonate (adapted from Dumelin and Tappel[23]).

A HISTORICAL PERSPECTIVE OF VITAMIN E DEFICIENCY ANEMIA

Although most neonates were found to be chemically vitamin E deficient at birth, several studies reported that term breast-fed infants increased their blood vitamin E levels to the adult range quickly, while term and premature infants fed artificial milk formulas continued to have low levels for months.[29,30,36] Wright et al[29] suggested that the greater vitamin E content of human milk as compared with artificial milk formulas accounted for this difference. In addition, although a number of investigators[30,37-39] had demonstrated that the increased RBC hemolysis measured with the hydrogen peroxide hemolysis test correlated with the presence of chemical vitamin E deficiency, a clinical vitamin E deficiency syndrome was not described until 1966. At that time, Hassan et al[40] reported the association of edema, especially of the legs, labia or scrotum, and eyelids, restlessness, watery nasal discharge, noisy and occasionally distressful or tachypneic respirations, skin lesions, and hematologic abnormalities with low vitamin E levels in premature infants. During the first six weeks of life, these infants had blood vitamin E levels that remained or fell below 0.45 mg/dL, increased erythrocyte sensitivity to hydrogen peroxide hemolysis, thrombocytosis, and peripheral blood smears that demonstrated characteristic morphologic abnormalities, specifically clumping of platelets, pronounced anisocytosis and poikilocytosis, and RBC fragments. Hassan and his co-workers[40] also noted that the edema, skin lesions, and hematologic abnormalities disappeared quickly following the administration of vitamin E and were not observed in infants fed the same diets supplemented with vitamin E. Since the affected infants had received formulas with a high PUFA content, a low vitamin E content, and vitamin E to PUFA (E:PUFA) ratios of 0.19 or 0.37 (refers to a ratio of the milligrams of dietary D-α-tocopherol to grams of dietary PUFA), the investigators suggested that the diet consumed by those infants had played an etiologic role in the development of this syndrome.

The relationship between the dietary content of PUFAs and the requirement for vitamin E had been the subject of several investigations[41-43] prior to the report of Hassan et al.[40] Essentially these and other studies had demonstrated that the requirement for vitamin E increased as the dietary content of PUFAs increased. After evaluating the average diet in the United States in 1960, Harris and Embree[43] proposed 0.6 as the "critical" dietary E:PUFA ratio. They suggested that diets with E:PUFA ratios greater than 0.6 generally protected against the development of chemical vitamin E deficiency. However, diets with ratios less than 0.6 were likely to contain an inadequate amount of vitamin E and would tend to permit the development of vitamin E deficiency. Therefore, since newborn infants, especially premature infants, have limited body stores of vitamin E at birth,[26] the findings[29,30,36,40] that they remained chemically vitamin E deficient and/or became increasingly deficient while being fed artificial milk diets with low E:PUFA ratios are understandable.

The report by Hassan et al[40] of a clinical syndrome associated with vitamin E deficiency was quickly con-

firmed. Oski and Barness[44] described the development of hemolytic anemia in chemically vitamin E-deficient premature infants aged 6 to 10 weeks who had been fed proprietary formulas. The anemia was characterized by marked reticulocytosis, pyknocytosis, and other abnormal RBC forms and by shortened RBC survival times. Administration of vitamin E to affected infants resulted in a prompt increase in the hemoglobin level and a fall in the reticulocyte count. Daily vitamin E supplements beginning on the third day of life prevented or markedly decreased the severity of the hemolytic anemia. Then, Ritchie et al[45] reported that widespread edema, hemolytic anemia, reticulocytosis, and thrombocytosis accompanied vitamin E deficiency in seven premature infants aged 4 to 8 weeks, who, as above, had also received commercial formulas. Again, these abnormalities were corrected with vitamin E therapy.

Following the publication of these reports, a number of controlled studies[46-53] have investigated the interrelationships between vitamin E, diet, and hematologic indices in the neonate. The association of vitamin E deficiency and hemolytic anemia and the ability to prevent their development with daily vitamin E supplements have been supported by some investigators[46-51] but not by others.[52,53] Chadd and Fraser[46] showed that although hemoglobin levels were higher at 8 to 10 weeks of age in infants whose diets were supplemented daily with 15 mg of vitamin E from birth, the finding was only significant in term infants. However, Jansson et al[51] found the opposite effect, noting that daily supplements with 15 mg of vitamin E from 10 days of age only produced a significant increase in hemoglobin concentration at 8 to 10 weeks of age in premature infants and not in term infants. Melhorn and Gross[47] evaluated infants less than 36 weeks of gestational age receiving a standard commercial formula and found that, at 6 to 10 weeks of age, infants who had been supplemented with 25 IU of vitamin E per day from the eighth to the 42nd day of life had significantly higher mean hemoglobin concentrations and lower reticulocyte counts and erythrocyte sensitivity to hydrogen peroxide than infants whose diets were not supplemented. They also noted that the daily administration of medicinal amounts of elemental iron (approximately 10 mg/kg/day) from the 15th to the 42nd day of life exaggerated the hemolytic process in infants not receiving vitamin E supplements. In addition, some iron-fortified formulas have been found to promote the development of vitamin E-deficiency anemia.[49-50] Although Lo et al[48] did not begin vitamin E supplements (10 mg/day) until about 40 days of age when signs of hemolysis first appeared, they demonstrated a significant hematologic improvement after two to three weeks of treatment. Although their data only confirmed that vitamin E deficiency anemia responded to vitamin E administration, they suggested that premature infants receive a daily supplement of 10 mg of vitamin E.

Conversely, Hashim and Asfour[52] reported that although term infants who remained vitamin E deficient while being fed a diet with an E:PUFA ratio of 0.19 had hematologic changes during the first month of life consistent with those abnormalities seen in premature infants with vitamin E deficiency hemolytic anemia, a severe hemolytic anemia did not develop. Furthermore, a spontaneous increase in hemoglobin concentrations at a rate comparable to infants who were fed a vitamin E-supplemented diet or who were breast fed was noted. In addition, while attempting to evaluate the interrelationships between vitamin E and linoleic acid in premature infants, Panos et al[53] demonstrated that vitamin E supplementation (10 to 25 mg/day) was unable to prevent the fall in hemoglobin concentration at 5 to 7 weeks of age and that it did not effect RBC survival as measured by the chromium 51 labeling technique.

It is evident from this brief review of these reports that neonates, especially premature neonates, appear to be at risk for the development of a clinical syndrome resulting from vitamin E deficiency. This risk is related to many factors, including the following: maternal nutrition and blood level of vitamin E; the infant's birth weight, gestational age, and body stores of vitamin E at birth; dietary content of vitamin E, PUFAs, and iron; the E:PUFA ratio; and the ability of the infant to absorb vitamin E from his diet. In addition, although most investigators have demonstrated that daily vitamin E supplementation prevents vitamin E deficiency anemia with significant increases in hemoglobin concentrations between 6 and 10 weeks of age, discrepancies exist in the results of these studies. Reasons for those discrepancies include differences in the composition of the formulas, iron intakes, the dose and preparation of vitamin E, and the duration of vitamin E supplementation. Bell[54] performed a critical analysis of these

controlled studies that had been designed to detect vitamin E effects on the RBC and/or to evaluate whether supplemental vitamin E could prevent the development of hemolytic anemia, and stated that the findings were conflicting, gave somewhat equivocal results, and demonstrated hematologic manifestations that were of limited clinical value. Since the interrelationships between vitamin E, iron, and PUFAs have been one of the more controversial issues in neonatal nutrition, they will be discussed in more depth after a brief review of vitamin E absorption in the neonate.

ABSORPTION OF VITAMIN E

Bieri and Farrell[7] have recently reviewed the data from human and animal studies in this area. Esterified forms of vitamin E are almost completely hydrolyzed prior to absorption. Bile is essential for its absorption, and the predominant route of absorption is via gastrointestinal lymphatics. Approximately 45% of a dose of vitamin E is absorbed into the lymph as unchanged α-tocopherol, whereas degraded metabolites in portal venous blood and in feces account for most of the remainder of the dose. Vitamin E enters the bloodstream from the lymph. It does not appear to have a specific lipoprotein carrier, and circulating vitamin E is primarily associated with the low-density lipoproteins in man. Although most tissues take up vitamin E rapidly and establish a concentration that is proportional to the logarithm of the blood concentration, adipose tissue continually accumulates vitamin E.[7] Machlin et al[55] recently reported that guinea pigs fed a vitamin E-deficient diet for two to four months mobilized vitamin E stores quickly from liver and slower from heart and muscle but did not deplete adipose tissue stores. They suggested that the rate of release of vitamin E from adipose tissue was not sufficient to maintain adequate blood vitamin E levels or to prevent signs of vitamin E deficiency.

As apparent in the above discussion, the absorption of vitamin E and of other fat-soluble vitamins is related to the ability to digest and absorb dietary fats, an ability that is limited in all neonates.[56] Although premature infants absorb fat less efficiently than term infants, the percent absorption increases postnatally during the early weeks of life.[56] In addition, human milk fat is better absorbed than cow's milk fat and unsaturated fatty acids are absorbed better than saturated ones.[56,57] Thus, the finding in previously noted studies that blood vitamin E concentrations rose rapidly in term breast-fed infants, but tended to remain low for several months in term and premature infants fed artificial milk-based formulas,[29,30,36] could be accounted for not only by the greater vitamin E content of human milk compared with formulas,[29] but also by the neonate's ability to absorb dietary fats.

Although Filer et al[58] demonstrated that premature infants absorbed an oral dose of 20 mg/kg of α-tocopherol or α-tocopheryl esters as well as did full-term infants, Melhorn and Gross,[59] found a relationship between gestational age and the ability to absorb vitamin E. With the use of a modification of the vitamin E tolerance index method described by Filer and associates,[58] these investigators determined vitamin E absorption curves in premature infants at 3 weeks of age after a single oral dose of 25 mg/kg of α-tocopheryl acetate and calculated the tolerance index with the following formula:

$$(T_s - T_B) \times 100/\alpha\text{-}T$$

where T_s is the serum tocopherol value at eight hours, T_B is the baseline serum tocopherol value, and α-T is the amount of α-tocopherol administered in milligrams per kilogram of body weight. Figure 3 graphically represents their data and reveals that intestinal absorption of vitamin E as measured by the vitamin E tolerance index increases with gestational maturity. In addition, vitamin E tolerance studies performed at 3, 6, and 10 weeks of life on six infants born with birth weights between 1,000 and 1,500 g and gestational ages between 28 and 32 weeks demonstrated a progressive improvement in the ability to absorb vitamin E with increase in postnatal age. Thus, this increase with postnatal age occurs as the premature infant is increasing his ability to absorb fats. These workers also demonstrated that although 3-week-old premature infants absorbed a water-soluble preparation of vitamin E (D-α-tocopheryl polyethylene glycol 1,000-succinate [TPGS]) significantly better than the fat-soluble preparation (D-α-tocopheryl acetate), 3-day-old term infants absorbed both preparations equally, as well as markedly better than the 3-week-old premature infants.[49] Recently, Bell et al[60] reported that premature infants less than 1 week old who weighed less than 1,500 g at birth absorbed a dose of 25 IU of either DL-α-tocopherol or DL-α-tocopheryl acetate equally well and that an adequate blood vitamin E level could be maintained in those infants with a daily dose of 25 IU of DL-α-tocopherol.

Melhorn and Gross[59] also found that mixing elemental iron (ferrous sulfate) with vitamin E (α-tocopheryl acetate) decreased the vitamin E tolerance index considerably, and thus suggested that oral administration of iron might interfere with the intestinal absorption of vitamin E. This finding was consistent with their previous data,[47] which demonstrated that daily administration of medicinal amounts of iron exaggerated the vitamin E deficiency anemia in premature infants not receiving vitamin E supplements. However, premature infants did absorb vitamin E better from a formula that was fortified with elemental iron (15.7 mg/L) and contained 10.0 IU of the water-soluble preparation of vitamin E (TPGS) and 6.6 IU of the fat-soluble preparation (D-α-tocopheryl acetate) than from a formula that was also iron-fortified (13.7 mg of elemental iron per liter), but contained only 13.5 IU of the fat-soluble preparation.[49]

Since Tantibhedhyangkul and Hashim[61] reported that total fat absorption was significantly improved in premature infants fed formulas containing medium-chain triglycerides (MCTs, fatty acids containing eight to 12 carbon atoms in chains), some formulas specifically designed for premature infants have included MCTs as a significant percentage of their total fat content. Although intestinal

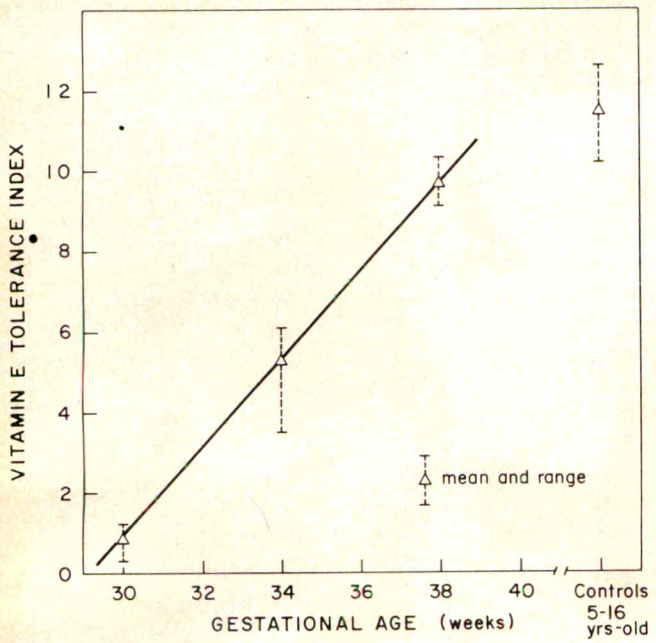

Fig 3.—Relationship between vitamin E tolerance index and gestational age. Tolerance index was determined in 3-week-old premature infants in following gestational age categories: 28 to 32 weeks, 32 to 36 weeks, and 36 to 40 weeks, and in healthy control children (adapted from Melhorn and Gross[59]).

absorption of vitamin E (D-α-tocopherol) in rats was enhanced by solubilization in MCTs as compared with long-chain triglycerides (LCTs, fatty acids containing 12 or more carbon atoms in chains),[62] Williams and Oski[63] recently reported that blood vitamin E levels in 6-week-old premature infants fed a formula containing 50% MCT and 50% LCT were not significantly different from vitamin E levels in similar infants fed a formula containing fats consisting completely of LCTs. However, since both of these formulas were fortified with iron, it is possible that the iron may have had a limiting effect on vitamin E absorption.

RATIO OF VITAMIN E TO POLYUNSATURATED FATTY ACID

As indicated in the discussion of vitamin E's mechanism of action, the requirement for vitamin E is related to the PUFA content of tissue lipids,[16] which in turn is influenced by the PUFA content of dietary lipid.[64-66] Although modification of tissue lipid PUFA concentration by changing the dietary content of PUFAs is quite complex,[64-66] increasing the dietary PUFA intake has generally been shown to increase the vitamin E requirement.[41-43] In addition, since the high PUFA content of many fats and oils is associated with a high total tocopherol content, although not necessarily with α-tocopherol content, diets including those foodstuffs may contain sufficient vitamin E activity to meet most of the increased requirements. As noted previously, Harris and Embree[43] proposed the use of an E:PUFA ratio of 0.6 as a guide to evaluate the adequacy of dietary vitamin E. However, they clearly stated that "experience has shown the impossibility of making flat rules for predicting the requirement of any nutrient without taking into account the rest of the diet, the environment, species, age or sex." Other investigators[7] have found that diets providing an E:PUFA ratio of 0.4 to 0.5 can produce an adequate vitamin E status in man. Witting[65] discussed the limitations of the recommendation of an E:PUFA ratio of 0.6,[43] and noted that although the vitamin E requirement is related to tissue PUFA content, tissue PUFA content might bear little relation to the dietary PUFA level, and thus, a 0.6 E:PUFA ratio is not applicable to all dietary regimens.

As with other tissues, the fatty acid composition of erythrocyte membranes is related to the fatty acid composition of the diet and has been shown to change readily with alterations in the dietary fatty acid content.[42,64,67,68] Hassan et al[40] and Hashim and Asfour[52] have demonstrated that feeding diets that were rich in linoleic acid to neonates resulted in an increase in the percentage of linoleic acid in erythrocyte lipids, the magnitude of that increase depending on the linoleic acid content of the formula. These investigators[40,52] also noted that the erythrocyte sensitivity to hydrogen peroxide hemolysis was highest at a time when the erythrocyte linoleic acid content was high and the blood vitamin E concentration was low. Since the diets given to these infants were also low in vitamin E (E:PUFA = 0.19 or 0.37), it was suggested that the increased erythrocyte susceptibility to peroxidation was related to insufficient antioxidant protection of membrane PUFAs and therefore that formulas with low E:PUFA ratios would predispose to the development of vitamin E deficiency anemia. In a recent study with premature infants weighing less than 1,500 g at birth, Williams et al[50] extended this observation by examining the effect of varying the dietary content of linoleic acid and iron while keeping the amount of vitamin E constant. They concluded that although formulas that contained adequate E:PUFA ratios could be fortified with iron, iron fortification of formulas with inadequate E:PUFA ratios increased the likelihood that vitamin E deficiency anemia would occur.

†Vitamin E as DL-α-tocopheryl acetate.
‡Milligrams of D-α-tocopherol per gram of polyunsaturated fatty acid; milligrams of D-α-tocopherol calculated from the international units of vitamin E contained in the formula as follows: milligrams of D-α-tocopherol per deciliter equals 0.67 mg/IU (international units of vitamin E per deciliter).
§Number in parenthesis is amount contained in iron-fortified formulation.

MEETING THE VITAMIN E REQUIREMENT OF THE NEONATE

On the basis of the reports[40,44,45] that vitamin E-deficiency anemia developed in premature infants who were receiving commercial formulas with high PUFA and low vitamin E contents, manufacturers of proprietary formulas increased the vitamin E content of their formulas to compensate for the use of fats with high percentages of PUFAs and to attain an adequate E:PUFA ratio. Although minimum dietary requirements for vitamin E have not been established, recommendations have been made by the American Academy of Pediatrics Committee on Nutrition.[69,70] The committee recommended that formulas designed for full-term infants contain a minimum of 0.3 IU of vitamin E per 100 kcal and at least 0.7 IU of vitamin E per gram of linoleic acid.[69] After consideration of the special needs of the premature infant, they recommended that formulas designed for premature infants provide a minimum of 0.7 IU of vitamin E per 100 kcal and at least 1.0 IU of vitamin E per gram of linoleic acid.[70] The use of a multivitamin preparation containing vitamin E was also suggested. Furthermore, since iron fortification of formulas high in PUFAs had been shown to increase the susceptibility of premature infants to vitamin E deficiency and hemolytic anemia,[49,50] the Committee on Nutrition[70] suggested that formulas for premature infants could provide either 0.1 mg or 1.5 mg of iron per 100 kcal and that if the higher level of iron was contained, sufficient vitamin E and a moderate level of PUFAs should be provided. Table 3 compares the composition of some of the current infant formulas with mature human milk.

In view of the Committee on Nutrition's[70] assessment of the nutritional needs of premature infants, most low-birth-weight premature infants in the Newborn Special Care Unit, Yale-New Haven (Conn) Hospital are fed an 81-kcal/dL (24-kcal/oz) commercial formula that contains a low level of iron and an appropriate proportion of vitamin E and PUFAs. The infants receive that formula until they weigh about 1,750 g, at which time they are switched to a 67-kcal/dL (20-kcal/oz) iron-fortified formula. In addition, each infant is given a daily supplement of a multivitamin preparation and an oral vitamin E preparation during their hospitalization. We have found that a daily oral dose of 50 IU of vitamin E (Aquasol E) for infants weighing less than 1,000 g and 25 IU for infants over 1,000 g usually maintains vitamin E blood levels within the normal adult range. Infants with cystic fibrosis, short gut syndrome, and other causes of chronic fat malabsorption receive at least 100 IU/day, which is continued following hospital discharge.

Although the composition of the present infant formulas appears to satisfy the recommendations of the Committee on Nutrition with respect to the interrelationships of vitamin E, PUFAs, and iron,[69,70] neonates who cannot be given enteral feedings and who require prolonged parenteral alimentation may remain chemically vitamin E deficient for long periods. Farrell[71] reported that the administration of parenteral fluids containing 1 IU of vitamin E per deciliter and providing 1 IU of vitamin E per kilogram per day took several days to correct vitamin E deficiency. We have studied serum vitamin E levels in two infants with short gut syndrome who received total parenteral alimentation containing 0.25 IU of vitamin E per deciliter and observed chemical vitamin E deficiency throughout the two- to three-month period of total parenteral alimentation (unpublished data). In addition, the effect of intravenous lipid emulsions on neonatal vitamin E requirements is not known. Although an analysis[71] of one proprietary lipid emulsion (Intralipid) demonstrated approximately 25 μg of total tocopherols per gram of lipid, γ-tocopherol, with low vitamin E activity, account for about 90% of that amount, while α-tocopherol account for only about 10%. Since lipid emulsions are rich in PUFAs, their use may predispose to vitamin E deficiency.

THERAPEUTIC IMPORTANCE OF VITAMIN E

The role of dietary vitamin E in preventing the development of vita-

min E-deficiency and hemolytic anemias in neonates has been reviewed previously and discussed in relation to the PUFA and iron content of the diet. Hemolytic anemia generally does not develop in infants with low blood levels of vitamin E unless they are receiving a diet that is rich in PUFAs, inadequate in vitamin E, and fortified with iron. Since most commercial infant formulas satisfy the recommendations of the Committee on Nutrition,[69,70] dietary-induced, vitamin E-deficiency hemolytic anemia does not occur frequently.

However, since vitamin E deficiency is associated with shortened RBC survival times,[44] several investigators have examined the effect of early vitamin E supplementation on the development of neonatal hyperbilirubinemia. Abrams et al[72] administered orally 100 mg of vitamin E (DL-α-tocopheryl acetate) daily from birth and, although plasma vitamin E levels were significantly increased, no significant effect on plasma bilirubin or hemoglobin concentration was noted during the first week of life. Conversely, Gross[73] recently reported that intramuscular (IM) administration of a total dose of 50 mg/kg of DL-α-tocopherol during days 1 to 3 of life resulted in a significant decrease in serum bilirubin concentration and in duration of phototherapy during the first week of life for infants with birth weights less than or equal to 1,500 g. This effect was less pronounced in infants with birth weights more than 1,500 g. Gross[73] suggested that this finding was consistent with a reduction in the accelerated RBC destruction characteristic of premature infants.

In addition to protecting erythrocytes, vitamin E appears to play a role in platelet and polymorphonuclear leukocyte (PMN) function and in immune response. Lake et al[74] demonstrated that the thrombocytosis seen in infants with vitamin E deficiency was associated with marked platelet hyperaggregability and that vitamin E supplementation resulted in a significant decrease in the platelet count and a normalization of platelet aggregation. However, Stuart and Oski[75] have also shown that vitamin E excess resulted in in vitro inhibition of platelet prostaglandin synthesis and aggregation. Recently, Boxer and coworkers[76] reported that although PMNs obtained from vitamin E-deficient rats had decreased chemotoxic and phagocytic activity, presumably secondary to oxidative damage, vitamin E-repleted PMNs had decreased bactericidal potency. Tengerdy and associates have described a significantly increased humoral immune response, as measured by the antibody plaque-forming cell test or by hemagglutination, in chicks[77] and mice[78] fed vitamin E-enriched diets.

Although these physiologic effects of vitamin E are achievable with dietary supplementation, two pharmacologic uses of vitamin E in the neonate have been proposed. These therapies are based on the findings of a large number of animal experiments that have demonstrated that vitamin E-deficient animals had more oxygen-induced damage to the lungs, the RBC, and the CNS than animals receiving a control diet[79-82] and that vitamin E treatment of vitamin E-deficient rats decreased the oxygen-induced lung injury.[82] Since chemical vitamin E deficiency is common in most neonates, vitamin E administration should increase endogenous antioxidant protection and therefore might reduce the incidence of retrolental fibroplasia (RLF) and bronchopulmonary dysplasia (BPD), two complications of oxygen use in the neonate. Johnson et al[83] administered an IM water-miscible preparation of DL-α-tocopheryl acetate to infants with a birth weight less than or equal to 2,000 g or to infants who required oxygen therapy and suggested that vitamin E reduced the incidence, severity, and duration of the acute stages of RLF. A clinical trial by Curran and Cantolino[84] also suggested a beneficial effect of vitamin E treatment on the incidence of RLF, and Phelps and Rosenbaum[85] have noted that vitamin E significantly reduced acute oxygen-induced retinopathy in newborn kittens. Recently, I and my co-workers[86] reported the results of a preliminary study that suggested that the IM administration of a water-dispersible preparation of DL-α-tocopherol during the acute phase of therapy for respiratory distress syndrome modified the development of BPD. This finding is supported by studies in newborn rabbits that demonstrated that vitamin E decreased morphologic evidence of acute oxygen-induced pulmonary injury after 72 hours of 100% oxygen exposure.[87] Since these clinical studies have drawn conclusions from a small number of patients, the randomized double-blind studies now in progress by these and other investigators will clarify whether vitamin E can prevent the development of RLF and BPD. So far, preliminary results from some of the studies[88-90] evaluating the efficacy of vitamin E in preventing the development of BPD have not confirmed the initial report.[86] However, since each of these investigations has used inspiratory pressures during positive-pressure mechanical ventilation that were markedly lower than the inspiratory pressures reported by me and my associates,[86] and since such limitation of the inspiratory peak pressure has been shown to decrease the incidence of BPD,[91] a large number of patients will be required to determine whether treatment with vitamin E can further decrease the incidence and severity of BPD. Milner et al[92] have recently emphasized the need for sample sizes large enough to minimize β error and to permit demonstration of the effectiveness of vitamin E in reducing the incidence of RLF and BPD.

Finally, although no side effects of pharmacologic vitamin E treatment have been noted in the neonatal reports other than local reactions at the injection sites,[83,86] side effects of high-dose vitamin E therapy have been described in adults and animals. In human subjects, high-dose vitamin E therapy has been associated with numerous subjective complaints and creatinuria[93] and exacerbation of a warfarin-induced coagulopathy.[94] In animals, side effects have included impaired wound healing[95] and anti-inflammatory activity[96] in rats and hepatic abnormalities and death in kittens.[97]

David F. Wender, MD, Ricardo Uauy, MD, and Joseph B. Warshaw, MD, provided editorial criticisms. Debra Camputaro prepared the manuscript.

CYCLAPEN®-W (cyclacillin)

Indications

Cyclacillin has less in vitro activity than other drugs in the ampicillin class and its use should be confined to these indications: Treatment of the following infections:

RESPIRATORY TRACT

Tonsillitis and pharyngitis caused by Group A beta-hemolytic streptococci

Bronchitis and pneumonia caused by *S. pneumoniae* (formerly *D. pneumoniae*)

Otitis media caused by *S. pneumoniae* (formerly *D. pneumoniae*) and *H. influenzae*

Acute exacerbation of chronic bronchitis caused by *H. influenzae**

*Though clinical improvement has been shown, bacteriologic cures cannot be expected in all patients with chronic respiratory disease due to *H. influenzae*.

SKIN AND SKIN STRUCTURES (integumentary) infections caused by Group A beta-hemolytic streptococci and staphylococci, non-penicillinase producers.

URINARY TRACT INFECTIONS caused by *E. coli* and *P. mirabilis*. (This drug should not be used in any *E. coli* and *P. mirabilis* infections other than urinary tract.)

NOTE: Perform cultures and susceptibility tests initially and during treatment to monitor effectiveness of therapy and susceptibility of bacteria. Therapy may be instituted prior to results of sensitivity testing.

Contraindications Contraindicated in individuals with history of an allergic reaction to penicillins.

Warnings Cyclacillin should only be prescribed for the indications listed herein.

Cyclacillin has less *in vitro* activity than other drugs of the ampicillin class. However, clinical trials demonstrated it is efficacious for recommended indications.

Serious and occasional fatal hypersensitivity (anaphylactoid) reactions have been reported in patients on penicillin. Although anaphylaxis is more frequent following parenteral use, it has occurred in patients on oral penicillins. These reactions are more apt to occur in individuals with history of sensitivity to multiple allergens. There are reports of patients with history of penicillin hypersensitivity reactions who experienced severe hypersensitivity reactions when treated with a cephalosporin. Before penicillin therapy, carefully inquire about previous hypersensitivity reactions to penicillins, cephalosporins and other allergens. If allergic reaction occurs, discontinue drug and initiate appropriate therapy. Serious anaphylactoid reactions require immediate emergency treatment with epinephrine. Oxygen, I.V. steroids, airway management, including intubation, should also be administered as indicated.

Precautions Prolonged use of antibiotics may promote overgrowth of nonsusceptible organisms. If superinfection occurs, take appropriate measures.

PREGNANCY: Pregnancy Category B. Reproduction studies performed in mice and rats at doses up to 10 times the human dose revealed no evidence of impaired fertility or harm to the fetus due to cyclacillin. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, use this drug during pregnancy only if clearly needed.

NURSING MOTHERS: It is not known whether this drug is excreted in human milk. Because many drugs are, exercise caution when cyclacillin is given to a nursing woman.

Adverse Reactions Oral cyclacillin is generally well tolerated. As with other penicillins, untoward sensitivity reactions are likely, particularly in those who previously demonstrated penicillin hypersensitivity or with history of allergy, asthma, hay fever, or urticaria. Adverse reactions reported with cyclacillin: diarrhea (in approximately 1 out of 20 patients treated), nausea and vomiting (in approximately 1 in 50), and skin rash (in approximately 1 in 60). Isolated instances of headache, dizziness, abdominal pain, vaginitis, and urticaria have been reported. (See WARNINGS) Other less frequent adverse reactions which may occur and are reported with other penicillins are anemia, thrombocytopenia, thrombocytopenic purpura, leukopenia, neutropenia and eosinophilia. These reactions are usually reversible on discontinuation of therapy.

As with other semisynthetic penicillins, SGOT elevations have been reported.

As with antibiotic therapy generally, continue treatment at least 48 to 72 hours after patient becomes asymptomatic or until bacterial eradication is evidenced. In Group A beta-hemolytic streptococcal infections, at least 10 days' treatment is recommended to guard against risk of rheumatic fever or glomerulonephritis. In chronic urinary tract infection, frequent bacteriologic and clinical appraisal is necessary during therapy and possibly for several months after. Persistent infection may require treatment for several weeks.

Cyclacillin is not indicated in children under 2 months of age.

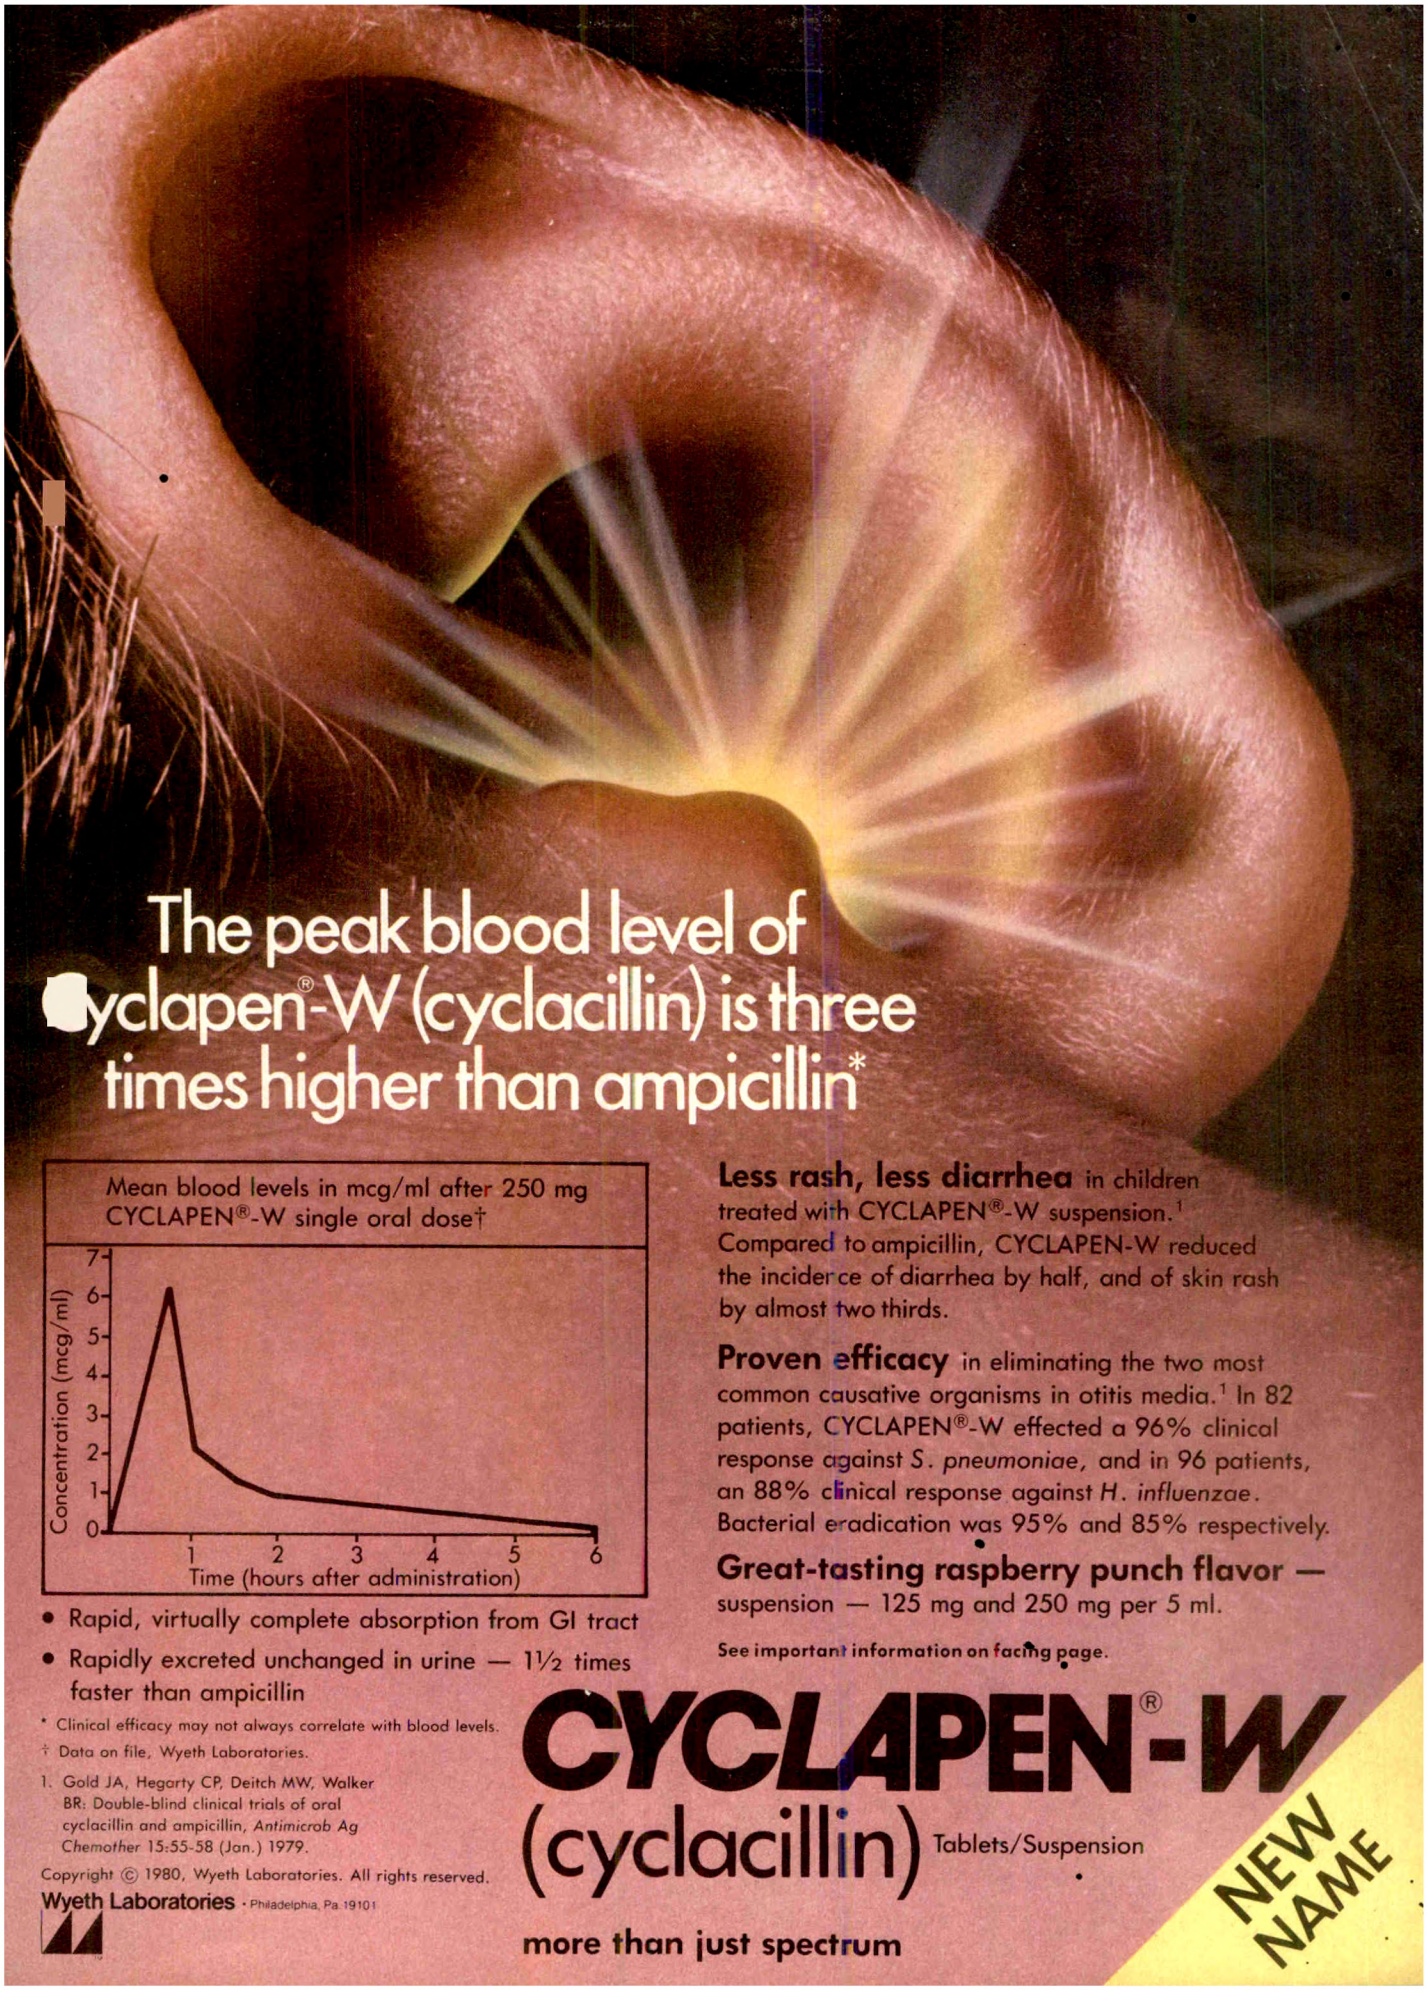
Patients with Renal Failure Cyclacillin may be safely administered to patients with reduced renal function. Due to prolonged serum half-life, patients with various degrees of renal impairment may require change in dosage level (see DOSAGE AND ADMINISTRATION in package insert).

Dosage (Give in equally spaced doses)

INFECTION	ADULTS	CHILDREN*
Respiratory Tract		
Tonsillitis & Pharyngitis	250 mg q.i.d.	body weight < 20 kg (44 lbs) 125 mg q.i.d. body weight > 20 kg (44 lbs) 250 mg q.i.d.
Bronchitis and Pneumonia		
Mild or Moderate Infections	250 mg q.i.d.	50 mg/kg/day q.i.d.
Chronic Infections	500 mg q.i.d.	100 mg/kg/day q.i.d.
Otitis Media	250 mg to 500 mg q.i.d.†	50 to 100 mg/kg/day†
Skin & Skin Structures	250 mg to 500 mg q.i.d.†	50 to 100 mg/kg/day†
Urinary Tract	500 mg q.i.d.	100 mg/kg/day

*Dosage should not result in a dose higher than that for adults.
†depending on severity

Wyeth Laboratories
Philadelphia, Pa. 19101



The peak blood level of Cyclapen®-W (cyclacillin) is three times higher than ampicillin*

Mean blood levels in mcg/ml after 250 mg CYCLAPEN®-W single oral dose†

- Rapid, virtually complete absorption from GI tract
- Rapidly excreted unchanged in urine — 1½ times faster than ampicillin

Less rash, less diarrhea in children treated with CYCLAPEN®-W suspension.[1] Compared to ampicillin, CYCLAPEN-W reduced the incidence of diarrhea by half, and of skin rash by almost two thirds.

Proven efficacy in eliminating the two most common causative organisms in otitis media.[1] In 82 patients, CYCLAPEN®-W effected a 96% clinical response against *S. pneumoniae*, and in 96 patients, an 88% clinical response against *H. influenzae*. Bacterial eradication was 95% and 85% respectively.

Great-tasting raspberry punch flavor — suspension — 125 mg and 250 mg per 5 ml.

See important information on facing page.

* Clinical efficacy may not always correlate with blood levels.

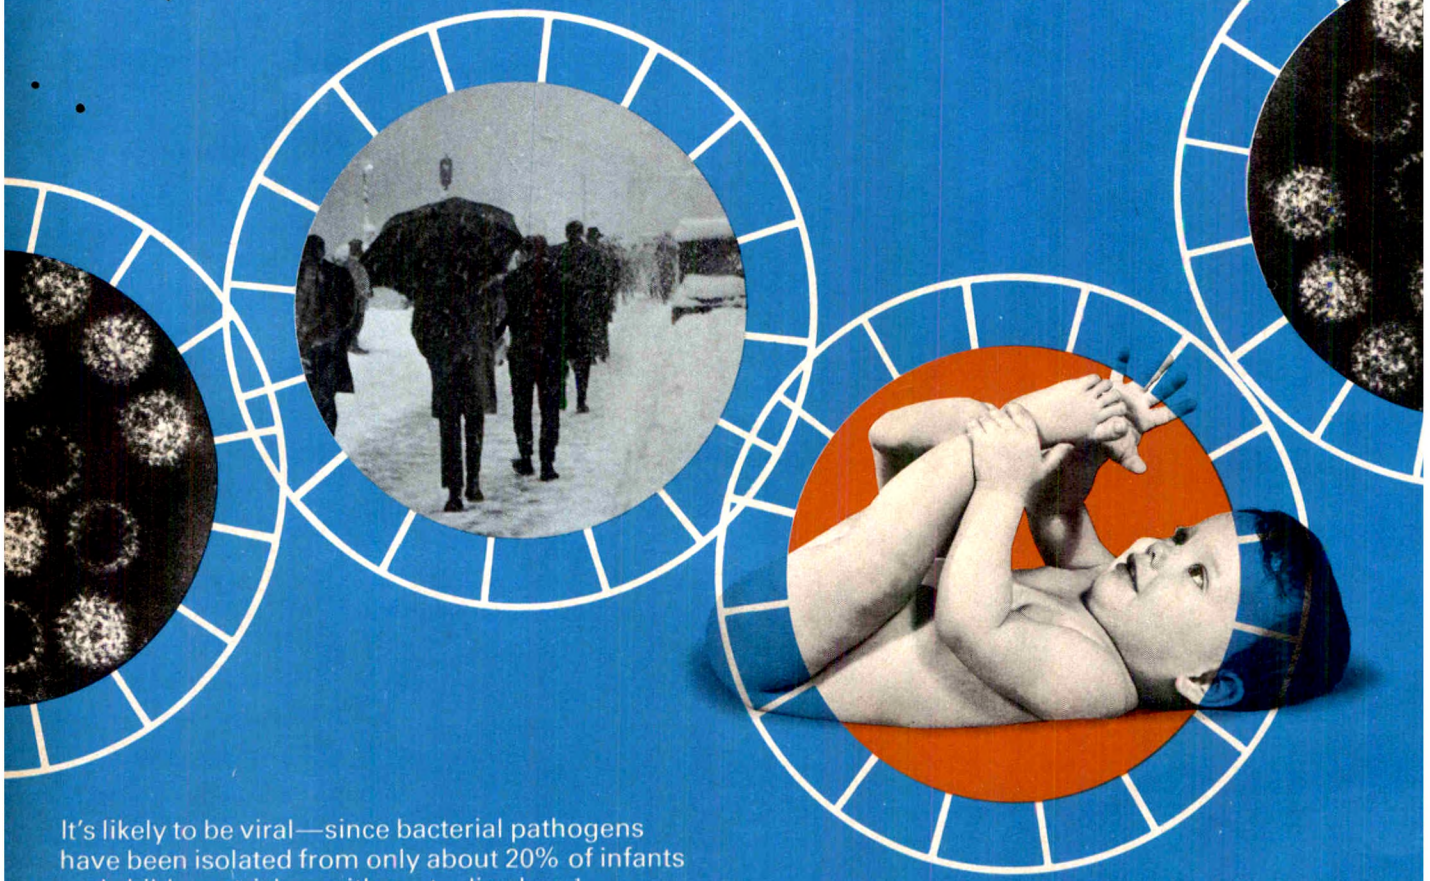
CYCLAPEN®-W (cyclacillin) Tablets/Suspension

NEW NAME

more than just spectrum

Infectious Diarrhea

Can you diagnose the cause?



It's likely to be viral—since bacterial pathogens have been isolated from only about 20% of infants and children stricken with acute diarrhea.[1]

Diarrhea and subsequent dehydration are common symptoms of infectious gastroenteritis, a serious disease which is responsible for hospitalization of more than 300,000 children in the U.S. annually. Today it is believed that about half of those children suffer from a specific type of viral infection—rotavirus.[2]

Rotavirus infections, singled out as the most important cause of non-bacterial gastroenteritis among children, are most prevalent now, during the winter months.

Rapid diagnosis is important.

Rotavirus infections are highly contagious and fast spreading, especially in the hospital setting. In one study, 20% of 60 infants at risk on hospital admission developed diarrhea within 72 hours.[3] An early definitive diagnosis removes uncertainty, eliminates unnecessary antibiotic treatment, and permits a rational approach to isolation and epidemiological control.

Presently most children with gastroenteritis are routinely tested for pathogenic bacteria. Now you can complete your workup with the first rapid viral diagnostic for rotavirus from Abbott Diagnostics...

Rotazyme™

- **Detects group specific antigen common to all rotaviruses.**
- **Confirmed diagnosis within hours.**
- **Simple enzyme immunoassay.**
- **As sensitive as conventional electron microscopy.**

The Association of 'Prune Belly' With Turner's Syndrome

It has been postulated that fetal abdominal distention causes abdominal muscle deficiency, or "prune belly." Although urethral obstruction was proposed as the most common mechanism, other possible pathways were suggested, including fetal ascites secondary to impaired lymphatic development in cases of 45,X Turner's syndrome.[1] We describe two patients with Turner's syndrome and prune belly and call attention to additional cases in the European literature that further delineate this association.

Report of Cases.—CASE 1.—This female infant was 2.8 kg at birth after the uncomplicated term pregnancy, labor, and delivery of her gravida 2, para 3, 23-year-old mother. The father was 25 years old. Turner's syndrome was diagnosed neonatally. Long leg casts were required for genu recurvatum from the ages of 2 to 8 months. She has a mild to moderate conductive hearing loss. Her development is grossly normal. She has had one urinary tract infection.

The mother reported that an intravenous pyelogram (IVP) showed one kidney smaller than the other. Two karyotypes were 45,X, without evidence of mosaicism. Family medical history was unremarkable.

At 3 years of age, the girl's height was 82.5 cm (below the third percentile), weight, 10.4 kg, and head circumference, 47 cm (tenth percentile). The facies was triangular with relative hypertelorism, epicanthus, and micrognathia. Auricles were prominent and cup-shaped, with hypoplastic helices. Angles of the mouth were downturned, the palate was narrow and high, and the neck short with bilateral webbing. The chest was broad with widely spaced nipples, pectus carinatum, and a short sternum. No heart murmurs were heard. Abdominal examination showed absent external and internal oblique muscles. Musculus rectus abdominis appeared normal and the transversus abdominis was at least partially present. Genitalia were normal.

The dorsa of the hands and feet were puffy. The elbows showed decreased extension and cubitus valgus. There was bilateral genu recurvatum and metatarsus varus. The nails were narrow and hypoplastic, the hands short and wide. Flexion creases were normal on the right and bridged on the left. Dermatoglyphics showed eight ulnar loops and two whorls. Deep tendon reflexes were 3+ on the lower extremities, 2+ on the upper.

CASE 2. This female infant was 1.95 kg at birth after the term pregnancy of her 21-year-old, gravida 2, para 1 mother. Amniotic fluid was meconium stained. There was respiratory distress secondary to pneumomediastinum, left pneumothorax, and right pleural effusion needing repeated taps, and finally a right-sided chest tube for presumed chylothorax. There were episodes of apnea and bradycardia. After 11 days she had a cardiac arrest and could not be resuscitated.

Her head circumference was 30 cm (below the third percentile), her ears low-set, and her neck webbed. Abdominal muscles were absent. Labia minora were prominent. There was distal edema and generalized hypotonia.

An IVP showed delayed visualization of a small left kidney and a right megaloureter without obstructive renal changes. The karyotype was 45,X,22ps+ (22ps+ is a normal variant).

Previous Cases.—Previous cases of Turner's syndrome and prune belly have been noted. These include Smith's patient[3] (presumably the same infant described by Pagon et al[1]), and possibly the child pictured on page 324 of Moore's book.[4] Two reports in the foreign literature antedating chromosome analysis fit the clinical picture. Partial summaries follow.

At the age of 23 months, Benesova's patient[5] weighed 11 kg and was 79 cm tall. Speech was limited to single words, the muscle tone was normal, the ears were angulated, the nasal bridge was broad, the palpebral fissures were oblique, the neck was short with bilateral skin folds, and there was mild hypertelorism. The thorax was wide, barrel-like, and excavated distally. The abdominal wall was soft with palpable circular defects in the muscle wall bilaterally, cranially extending to the rib cage, caudally 2 cm below the umbilicus, medially to the rectus muscle edge, and laterally to the ventral axillary line. With crying, there was a mild bulging the size of a tangerine on the right and the size of a walnut on the left. There was edema of the dorsal arms, basal digits, and the dorsum and phalanges of the feet. There was a mild crural atrophy and a mild convergent strabismus.

The patient described by Jeune and Jacquot[6] was one month premature, weighed 3.0 kg at birth, and had a bronchoalveolar pneumonia at 14 days of age. The neck showed pterygium colli with cutis laxa. There was cutis laxa of the extremities and a lymphangiectatic edema of the right leg. There was aplasia of the left *jumeau interne* (translation uncertain) muscle, epicanthus, a gothic palate, and hypoplastic nipples, but no cubitus valgus or joint limitations. Isolated dextrocardia was noted. The abdominal musculature showed total aplasia. Cystography showed left ureterovesical reflux. She died of the lung disease after ten days.

Comment.—These cases support the concept of an etiologically distinct variant of prune belly syndrome in 45,X female infants. Urinary tract anomalies tended to be milder than those in typical male infants with the syndrome.[7] Similar findings are common in Turner's syndrome,[8] and their presence is probably coincidental rather than causative.

In these cases, Turner's syndrome was recognized early, and congenital stigmata were prominent. Probably the majority of XO female infants are diagnosed after the failure of menstruation,[9] and phenotypic manifestations are often mild.[8] The most obvious congenital findings are swellings of the dorsa of the hands and feet and webbing of the neck, all probably related to lymphatic abnormalities. The presence of such obvious findings in all known cases of prune belly, and the absence of karyotyped Turner's syndrome in females ascertained with abdominal muscle hypoplasia but without such stigmata,[2] suggest a role for the lymphatic abnormality, although whether this is direct or mediated through the production of ascites is uncertain.

The variability seen is of interest. In all cases, the rectus muscles were spared, suggesting a differential sen-

sitivity to pressure. In the male, variability may depend on the anatomy of the distended urinary tract rather than on underlying muscular vulnerability.

Fetal Damage due to Aminopterin Ingestion: Follow-up at 17½ Years of Age

In 1962, a female infant was delivered at 39 weeks' gestation to a mother who had attempted to induce abortion by ingesting an unknown amount of aminopterin sodium between days 55 and 58, with profound toxic effects, including epistaxis, loss of hair, and ulcerations of the mouth and skin. Failing to abort and realizing the danger of her fetus, she demanded an abortion but was refused. Her toxic symptoms subsided before delivery. The status of the child has been reported at birth, at 33 months, and at 9 years of age.[1,2] This is an update on her amazing improvement at 17½ years of age.

The Patient.—At birth her weight was 1,750 g, and her appearance resembled an identically injured neonate described by Warkany et al[3] who had died at 24 hours of age. Our patient was not expected to live but improved after several days. Her globular skull was almost devoid of ossification except for a small area at the base; the orbita were poorly formed; the eyelids were everted; and the eyebrows were deficient and lacked pigmentation in the lateral half. Her hair was curiously backswept, as was that of the patient described by Warkany et al.[3] She had marked micrognathia and extraordinary foreshortening of her forearms and legs, and both radial heads were defective and subluxated.

At 4½ and at 9 years of age, there had been surprising improvement. Her linear growth and weight gain had been at about the 2.5 percentile. At 17½ years of age, she is a slender, short (150 cm) young adult, weighing 40.4 kg (her mother is similarly proportioned). She does not appear dwarfed. Her skull has ossified normally (circumference, 50 cm); the previous frontal bossing is no longer present, and the metopic suture is closed. Her hair is blonde and abundant, and the eyebrows are normally present but less pigmented on the outer half. Micrognathia is still marked; her teeth are crowded and protruding, but she is receiving skilled but difficult orthodontic care. Her orthodontist (Carl A. Kuhn, DDS), reports that her mandible, which usually grows very fast in infancy, has not kept pace with her extremities and it has been necessary to extract several teeth to accommodate her dentition to her jaw size. Her facial appearance is not unattractive. The black nevus below her mouth is unchanged. Her extremities are now normal in length, proportion, and mobility. Secondary sex characteristics and sexual development are normal; menstruation began at 11½ years of age and is normal.

This girl is a ward of the court and has had the advantage of care from devoted foster parents. Earlier in childhood, she was handicapped socially by her peculiar appearance but she now seems well adjusted and has many friends. Except for arithmetic, at which she is poor, she does acceptably well at school. Numerous psychometric studies at school have produced results within a normal but rather low range. She is not especially athletic but joins in normal physical activities involving running and throwing. She plays the organ acceptably. In short, this child who was so badly damaged at birth has gained to acceptably normal young-adult status.

Comment.—When this child was initially described she was believed to be the only survivor past neonatal life of this disastrous fetal damage. However, several similar patients have since been identified.[4-6] Two personal communications indicate cases so similar that a common etiology seems likely.

Apparently, all of the mothers of similarly involved children took aminopterin at about the same period in pregnancy and suffered similar side effects. The infants are so similarly affected that one could suspect the etiology in any others with similar defects. Uniformly, there have been abnormalities in skull development, facial defects, micrognathia, and often palatal defects, as well as maldevelopment of long bones with defects of linear growth and bony development. All the described adult survivors are remarkably similar. None has had defective mental capacity; some are even reported as being quite superior.[4]

It is unlikely that aminopterin will ever again be used as an abortifacient. Nevertheless, this inadvertent pharmacological experiment in teratogenesis might conceivably be repeated in the treatment of malignant neoplasms during pregnancy or other situations. The resemblances of the cases involved either in early infancy or in adult life are so similar that their encounter might suggest etiology from the same agent or a similar one. Growth and repair are quite similar phenomena. Many deformities present at birth from teratologic or genetic influences persist relentlessly in later years. It is amazing that such a profound degree of damage due to aminopterin could be overcome to a considerable extent during growth from birth to adulthood.

Severe Meningococcal Disease Caused by Serogroups X and Z

The minor serogroups of *Neisseria meningitidis* (X,Y, and Z-W135 and 29 E) were initially considered to be of low virulence and were thought to produce very mild clinical disease. However, since 1974, many reports have appeared in the literature that clearly document that severe meningococcal disease does occur with group Y and group W135.[1-7] To our knowledge, there have been no previous reports of severe meningococcal disease in children caused by serogroups X or Z. We report two such cases. One case is that of severe meningococcemia and meningitis with disseminated intravascular coagulation (DIC) caused by group X *N meningitidis* and one is that of fatal fulminant meningococcemia and meningitis with DIC caused by group Z *N meningitidis*.

Report of Cases.—CASE 1.—A 9-month-old infant was well until one day prior to admission, when she experienced fever, vomiting, and a rash. The child was seen at a local emergency room with a temperature of 40.5 °C. She was diagnosed as having an upper respiratory tract infection and sent home. The rash began to spread and the child was seen at another hospital and again sent home. By this time, the child was covered with "purple bruises" and was limp and very lethargic. The parents brought the child to the University of Mississippi Medical Center (UMC), Jackson.

On admission, the child was lethargic with extensive purpuric lesions on the face, trunk, and extremities. The temperature was 37.5 °C, the pulse rate was 200 beats per minute, the respiratory rate was 20/min, and the blood pressure (BP) was 100/60 mm Hg. The child's fingertips were cyanotic and cold.

Laboratory Data.—The CSF revealed 42 cells with 93% neutrophils. The CSF protein level was 17 mg/dL and the glucose level was 75 mg/dL. The CSF Gram's stain revealed Gram-negative diplococci. The WBC count was 12,400/cu mm. The coagulation studies revealed a platelet count of 310,000/cu mm, prothrombin time of 18 s with a control of 11 s, partial thromboplastin time of 60 s with a control of 35 s, and thrombin time of 15 s with a control of 14 s. Fibrin split products were positive in dilutions of 1:5 and 1:20. Blood and CSF cultures revealed N *meningitidis* group X.

The child was treated with aqueous penicillin G and also received steroids. Her hospital course was marked by extensive skin loss and autoamputation of the fingers of the right hand and the tips of the second, fourth, and fifth fingers of the left hand.

CASE 2.—A 2-year-old boy was well until two days prior to admission, when he experienced a cold manifested by rhinorrhea. One day prior to admission, he was irritable and had a low-grade fever, but continued his normal activity. Four hours prior to admission, when put to bed, he was noted to have one "red spot" beneath the left eye but was otherwise well. He was checked three hours later, and was noted to have a high fever and a generalized rash. He was brought to the UMC.

On admission, the child was unresponsive, with a BP of 70/0 mm Hg and temperature of 41.7 °C. There was an extensive purpuric rash. The child experienced generalized seizure activity. He was treated with hydrocortisone sodium succinate (Solu-Cortef), aqueous penicillin G, anticonvulsants, and an exchange transfusion. However, his condition deteriorated rapidly and he died within hours of admission.

Laboratory Data.—The WBC count was 5,500/cu mm with 2,200 neutrophils and 1,100 band forms. The CSF cell count was 1,260, with a predominance of neutrophils. The CSF protein level was 200 mg/dL and the glucose level was 6 mg/dL. Coagulation studies revealed a platelet count of 29,000/cu mm, prothrombin time of 22.3 s with a control of 12.3 s, and a partial thromboplastin time of 74.3 s with a control of 29.6 s. Fibrin split products were positive at dilutions of 1:5 and 1:20. Electrolyte values were normal. Cultures of CSF and blood were positive for *N meningitidis* Z.

Comment.—The clinical disease in these two patients was indistinguishable from that produced by the major serogroups of *N meningitidis*. In both patients, the disease was that of fulminant meningococcemia and meningitis with DIC. One child (case 1) suffered severe thromboembolic phenomena with infarction of the fingers on both hands. The other child (case 2) arrived in shock and died shortly after admission.

Serogroups X and Z must be added to the growing list of *N meningitidis* serogroups capable of producing severe clinical disease. It is reasonable to assume that any of the serogroups are potentially pathogenic for man.

The efficacy of group-specific meningococcal vaccination has been well documented.[8-11] The increasing frequency of serious illness caused by the minor serogroups may be of major importance if vaccination programs are to be effective in controlling epidemic disease. To broaden the potential protection afforded by meningococcal vaccination, a polyvalent vaccine that includes groups A, C, and Y has been developed and shown to be effective in clinical trials.[12] A polyvalent meningococcal vaccine affording protection against all serogroups is not yet available, but with the changing serogroups producing severe meningococcal disease, such a vaccine may become necessary if epidemic meningococcal disease is to be controlled.

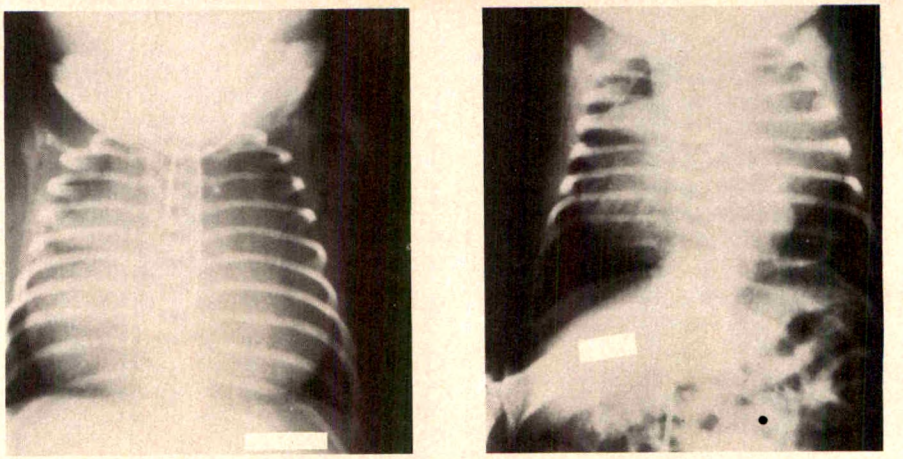
Intrapericardial Teratoma: A New and Treatable Cause of Hydrops Fetalis

Nonimmune hydrops fetalis, characterized by the accumulation of interstitial water (anasarca) in the absence of isoimmunization, has been associated with at least 38 different pathologic entities, accounting in 1970 for approximately 20% of reported hydropic infants.[1-3] Surprisingly, the association of hydrops and congenital heart disease is an uncommon observation,[1] but has been reported sporadically in patients with premature closure of either the patent foramen ovale or ductus arteriosus, Ebstein's anomaly of the tricuspid valve, severe pulmonary insufficiency, both right and left ventricular endocardial fibroelastosis, myocarditis, cerebral, pulmonary, and abdominal arteriovenous fistulae, hypoplastic left heart syndrome, and cardiac arrhythmias.[1] Interestingly, intrapericardial teratomas have been associated with pericardial effusion,[4-8] usually with cardiac tamponade in infants,[4,5,8] but not with hydrops. This report presents the clinical features of a newborn with an intrapericardial teratoma and hydrops fetalis, and discusses the incidence, diagnosis, and management.

Report of a Case.—The patient weighed 3,090 g at birth, the product of a 33-week gestation complicated by polyhydramnios. His mother was 35 years old, gravida 4, para 2, abortus 1, O Rh-negative. At birth he was severely hydropic and had Apgar scores of 2 and 4 at one and five minutes, respectively. His systolic blood pressure was 54 mm Hg; pulse rate, 120 beats per minute; and respirations, 50/min. There was no pulsus paradoxus. Breath sounds were diminished bilaterally. Heart sounds were distant and regular. There were no murmurs. The abdomen was tense and distended. There was severe, generalized edema. By Dubowitz's estimate, fetal age was 34 weeks.

The hematocrit value was 43%; total serum protein level, 2.6 g/dL; BUN level, 13 mg/dL; and serum creatinine concentration, 1.4 mg/dL. The patient's blood type was O Rh-positive; the Coombs' test was negative. Blood, urine, and CSF bacterial cultures were sterile. No virus was grown from either the nasopharynx or stool. Immunoglobin concentrations were normal, and the toxoplasmosis, other (coxsackie, echo, enterovirus), rubella, cytomegalic inclusion, and herpes (TORCH) screen was negative. The chest roentgenogram demonstrated right-sided pleural effusion, with a hazy appearance to the lung fields bilaterally. The heart silhouette was massively enlarged (Figure). An ECG disclosed a right axis, sinus rhythm, and small QRS complexes in all 12 leads. An echocardiogram showed a large amount of fluid in the anterior pericardial space. Initial treatment consisted of fluid restriction and furosemide. Within one week his weight decreased to 2,048 g.



Left, Chest roentgenogram demonstrates massive midline radiopacity. Right, Following intrapericardial instillation of 20 mL of carbon dioxide, note large tumor mass to patient's right, displacing heart and thymus to left.

Two pericardiocenteses yielded 42 mL of fluid; radiologic examination showed no change in the cardiac silhouette. On the 19th day, the patient underwent catheterization of the right side of the heart. The heart and pulmonary arteries were displaced to the left. The foramen ovale could not be crossed. Right atrial pressure was as follows: a wave, 10 mm hg, and v wave, 5 mm Hg (mean, 3 mm Hg); right ventricular pressure, 65/10 mm Hg; and pulmonary artery pressure, 33 mm Hg systolic (mean, 16 mm Hg). There were no left-to-right shunts. Angiograms in the right ventricle, right atrium, and main pulmonary artery demonstrated displacement of the heart to the left, with a concavity to the right atrial silhouette suggestive of an extrinsic mass. After instillation of 20 mL of carbon dioxide into the pericardial space, the chest x-ray film (Figure, right) disclosed a filling defect in the right anterior and superior pericardial space displacing the thymus and heart to the left. The systolic pressure difference between the right ventricle and pulmonary artery was attributed to compression from the intrapericardial mass.

When the patient was 23 days of age, an intrapericardial tumor adherent to the pericardial reflection at the aorta was excised. The 8 × 6 × 5-cm tumor was estimated to be four to five times larger than the heart. At histologic examination, the mass contained immature neurologic tissue (scattered areas of choroid plexus, and eye), colonic epithelium, respiratory tract epithelium, cartilage, and squamous mucosa, diagnostic of a teratoma. No malignant elements were seen. His postoperative course was complicated by aspiration pneumonia that responded to medical management. He has continued to do well at age 20 months.

Comment.—Extensive reviews of hydrops fetalis[1,2] fail to cite intrapericardial teratoma as a cause of hydrops. Similarly, a review of 37 cases of intrapericardial teratoma did not disclose any patients with hydrops.[4] We have identified an additional 14 reported patients with intrapericardial teratoma and pericardial effusion; none has had hydrops fetalis.[5-9,10-13]

Intrapericardial teratomas are rare. Teratomas account for only 10% of mediastinal masses in children.[14] In a recent review of several series of teratomas in children,[14] the anterior mediastinum accounted for only 3% to 5%, and none was reported to be within the pericardium. During an eight-year period, according to D. C. Fyler, MD (written communication, Dec 12, 1978), the New England Regional Infant Cardiac Program identified three patients with an intrapericardial teratoma among 3,376 infants with critical congenital heart disease, a rate of approximately one in 10,000 infants per year with critical heart disease. Nonetheless, at least 50% of the patients with intrapericardial teratomas are initially observed within the first three months of life.[9] Malignant degeneration at the time of original diagnosis is unusual; Reynolds et al[4] described two among their 37 collected cases; we were able to identify only one more[10] in the 14 additional patients. These three patients died with severe local extension of disease.

The pathogenesis of hydrops fetalis is unknown.[1] Although hydrops fetalis is associated with an increased incidence of cardiac malformation, the converse is not true, and no etiologic

relationship between the two has been established.[3] Nonetheless, postulated mechanisms include anemia, congestive heart failure, hypoalbuminemia, decreased colloid oncotic pressure,[1] and, in the patient with congenital structural heart disease, right ventricular obstruction.

Hypoproteinemia was present in our patient (2.6 g/dL); the resultant calculated serum albumin concentration of 1.6 g/dL (60% of total protein) almost certainly resulted in a low oncotic pressure, and no doubt contributed to the anasarca. In addition, the estimated tumor-cardiac ratio (4 to 5:1) very likely produced severe right-sided obstruction at the level of the right atrium, further contributing to the development of hydrops.

The diagnosis of an intrapericardial tumor should be suspected early in the course of an infant with unexplained hydrops and a large heart and should lead to early echocardiogram[6] and cardiac catheterization. Two-dimensional echocardiography, radioangiography,[9] and pneumopericardiocentesis[4,8] may render catheterization unnecessary. As Reynolds and colleagues[4] have emphasized, the treatment is careful diuresis followed promptly by surgical excision. In most patients,[4] the tumor is attached to the heart or great vessels by a fibrous stalk, and bypass of the circulation is unnecessary. Nonetheless, hemorrhage is the major surgical complication. Of the 52 (including ours) patients described in the literature, 35 have been operated on, with 79% survival. There are no reported recurrences of intrapericardial tumor. Thus, despite the low frequency of the lesion, accurate diagnosis is essential as treatment is potentially curative.

Clostridium Infection in Mother and Infant

Clostridium infections in newborns, excluding neonatal tetanus, are rarely reported.[1-7] The case described here is of special interest because both the mother and infant had classic, symptomatic *Clostridium* septicemia and both recovered.

Report of a Case.—A 19-hour-old, 3,080-g, female infant was transferred to North Carolina Memorial Hospital (NCMH) because of jaundice, dark urine, and maternal fever. The infant had been delivered by emergency cesarean section for fetal distress of a 25-year-old, O-positive, primagravida after an uncomplicated term pregnancy. An amniotomy performed 2½ hours prior to delivery had yielded clear fluid. Apgar scores were 6 and 5 at one and five minutes, respectively, after birth. Initial tachypnea and grunting had resolved by 1 hour of age. At 12 hours of age, the infant was jaundiced and passing dark urine. Her total serum bilirubin level was 10 mg/dL (direct bilirubin level, 1.0 mg/dL), and hematocrit value 49%. Cord, throat, stool, blood, and urine cultures had been taken, and 150,000 units of penicillin G potassium and 20 mg of kanamycin sulfate had been given intramuscularly (IM) prior to transfer.

Physical examination and admission to NCMH was normal except for jaundice. There was no fever. The hematocrit value had fallen 12 points over seven hours to 37%. The WBC count was 29,000/cu mm, with a shift to the left. Toxic granulations were seen. The infant's blood type was A positive; the direct Coombs' test was negative, and the indirect Coombs' test was weakly positive for anti-A antibody. The urine was dark brown with marked hemoglobinuria and bilirubinuria, but RBCs were not seen on microscopic examination. The total serum bilirubin level had risen to 15.3 mg/dL. Serum electrolyte values were normal, but the BUN level was 21 mg/dL and the serum creatinine concentration was 1.7 mg/dL. There were scattered patchy infiltrates in the right upper and right lower lobes on chest roentgenogram.

The infant was treated with ampicillin sodium, 150 mg/kg/day, and kanamycin sulfate, 15 mg/kg/day, both given IM. Phototherapy was administered for four days. The maximum total serum bilirubin level was 17.1 mg/dL. On the second day of hospitalization, both the infant's and mother's blood cultures yielded *Clostridium perfringens*. Ampicillin and kanamycin therapy was discontinued, and penicillin G potassium, 200,000 units/kg/day, was administered IM for ten days. The infant remained asymptomatic, with a stable hematocrit value of 34%. Repeated measurements of BUN and serum creatinine levels gave normal values; the follow-up chest roentgenogram at 1 month of age was also normal.

The mother's illness was more severe. Twelve hours postpartum, her temperature was 39.5 °C. She was jaundiced, with a total serum bilirubin level of 6.6 mg/dL. Her WBC count was 15,200/cu mm. Her hemoglobin level had fallen from 12 to 5.7 g/dL, and there was evidence of hemolysis on peripheral blood smear. Marked hemoglobinuria was present. She was transfused with packed RBCs and treated for ten days with aqueous penicillin G and clindamycin phosphate given intravenously. The abdominal wound healed without complications, and she was discharged on the tenth postpartum day. Examination of the placenta showed no evidence of inflammation. Placental cultures were not obtained. Chemical identification and disk sensitivities on the transferred organisms confirmed the identity of the *C perfringens* blood culture isolate from mother and infant.

Comment.—*Clostridium* species can produce major disease in adults, but several reports have noted a poor correlation between the presence of *Clostridium* in soft tissues or in the bloodstream, and clinical sepsis.[8-10] *Clostridium* species are isolated infrequently from neonates, but when

present are found most often in peritoneal, wound, and blood cultures.[11] Recently, *Clostridium* species have been associated with neonatal necrotizing enterocolitis.[12]

The present case of pure *Clostridium* infection in the newborn is the ninth reported, but the first, to our knowledge, confirming simultaneous maternal and infant septicemia. It also appears to be the first neonatal case that demonstrates the classic features of symptomatic adult *Clostridium* septicemia: active hemolysis and resultant hyperbilirubinemia and hemoglobinuria. In general, the presenting signs and symptoms do not discriminate *Clostridium* infection from any other generalized infection in the newborn. Jaundice and/or elevated indirect bilirubin values are mentioned in six of the nine reported cases.[1,2,4-6] Seven (77%) of nine infants had septicemia proved by culture.[1,2,4-7] Two infants had omphalitis only,[1,3] and two had sepsis and omphalitis.[4,7] *Clostridium perfringens* was the species isolated in six (67%) of the nine cases. The mortality was 44% (4/9), and one survivor is severely handicapped.[4] In the two earliest cases,[1] antibiotics were administered together with antiserum. Currently, penicillin in dosages of 50,000 to 200,000 units/kg/day is the drug of choice for *Clostridium* infections, although other antibiotics often are added to cover coinfecting organisms. In cases of tissue infection, it is essential to debride the necrotic material.

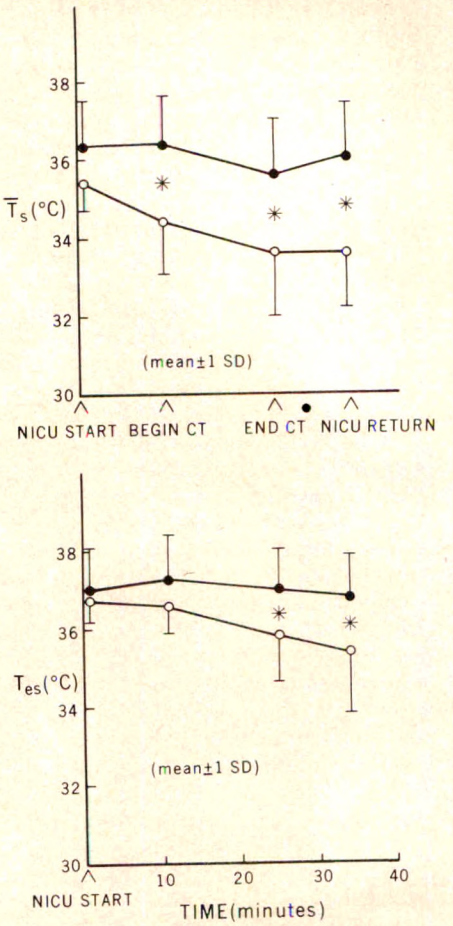
Temperature Control During Computerized Tomography and In-Hospital Transport of Low-Birth-Weight Infants

Computerized tomography (CT) is being used with increasing frequency for the diagnosis of intracranial pathological conditions in low-birth-weight infants. To ensure reliable computer function, ambient temperature in the scanner room is maintained below 23.9 °C. This precludes the use of radiant heaters and subjects small infants to considerable cold stress during the procedure.

We studied temperature control during in-hospital transport and CT scan in 14 infants with a heated mattress as the heat source.

Patients and Methods.—Fourteen infants, with gestational ages between 26 and 34 weeks and birth weights 700 to 2,220 g, were studied two to 63 days after delivery when undergoing CT brain scans. Eight infants received ventilation assistance during the procedure and during transport to and from the Neonatal Intensive Care Unit (NICU). Skin temperatures were measured at six sites, and mean skin temperature was calculated with weighted factors from measurements of surface area.[1] Core temperature was measured in the esophagus.

Six infants were studied using the heated mattress as the sole source of heat (group 1). Eight infants were warmed by the mattress in addition to being wrapped in bubble plastic packaging material (group 2). Mean weight (± SD) at the time of the study was 1,352 ± 620 g in group 1 and 1,098 ± 587 g in group 2. All infants wore wool boots and caps. The infants were transported in their own single-walled incubator, with full monitoring throughout the procedure.



Mean skin temperature ($\bar{T}_s$) and esophageal temperature (T_{es}) of infants during in-hospital transport and computerized tomographic (CT) scan. NICU indicates neonatal intensive care unit. Closed circle indicates heated mattress plus bubble plastic bag (n = 8); open circle, heated mattress (n = 6). Asterisk indicates $P<.05$.

Results.—The Figure shows the mean skin and esophageal temperatures recorded before, during, and after CT scan. A combination of the heated mattress and a simple insulating bag (group 2) maintained body temperature throughout (although these infants were considerably lighter), whereas a significant fall in body temperature occurred by the end of the procedure in the infants in group 1. Hyperthermia occurred transiently in two infants in group 2 before they left the NICU (core temperature, 38.1 °C and 38.4 °C, respectively).

Comment.—Both the heated mattress and the transparent baby bag have been used previously with success in situations where the infant is exposed to thermal stress.[2,3] After a two-hour recycling process when ener-

gy is stored in the liquid phase, the heating system is activated by injection of a small amount of catalyst into the liquid contents of the mattress. A reaction characterized by an exothermic latent heat of recrystallization occurs within a few seconds and will maintain the temperature of the mattress at 40 °C for two to four hours, depending on the ambient temperature. Thirteen of the neonates who required CT brain scans had sustained an intraventricular hemorrhage and were critically ill, so their mechanisms for thermal homeostasis were inadequate even with minor cold stress. This sort of stress is unavoidable during the performance of a CT scan, and the combination of the heated mattress and bubble plastic bag was effective in preventing a fall in body temperature, both during the scan as well as during the transport of the infant. The mattress by itself did not prevent hypothermia (Figure). The availability of a portable heat source together with a simple insulating blanket made it possible to transport these infants without removing them from their own incubators to a transport incubator, thus simplifying the whole process considerably. The potential for hyperthermia to develop when this technique is used necessitates close monitoring of the infant's temperature.

This is a simple, efficient, inexpensive, and convenient method for maintaining body temperature in low-birth-weight infants during transport and during the performance of procedures in the hospital.

60 YEARS AGO IN THE AJDC

Some Phases of the Pathology of Nutrition in Infancy

In this paper read before the Harvey Society is an extensive review of the current understanding of acute diarrhea (toxicosis or cholera infantum) and of more chronic marasmus (infantile atrophy, athrepsia). Both conditions are common and cause large numbers of infant deaths. Since there is little anatomic pathology observed in these disorders, a derangement in the chemical and physiologic process must be suspected.

In the acute form, rapid loss of weight occurs with sharpening of the features, sunken eyes, loose skin, and dry lips and mouth. Respirations are deep with "air hunger," thought due variously to circulating abnormal acids, a loss of base, or a loss of renal phosphate excretion. The gray pallor and prostration with a weak thready pulse are caused by diminished blood volume due to drying of the blood by excessive water loss. There is some similarity to surgical shock except that plasma proteins are found to be high in diarrhea. Reducing substances, detected in the urine, have been shown to be glucose, galactose, or lactose. The latter, not altered in the body outside of the intestinal tract, is then excreted in the urine. The fever which so commonly occurs has been thought by Finkelstein due to the effect of a pyrogen, but Woodyatt and his associates felt it was due to a decrease in the amount of water available for evaporation since the healthy infant has been shown to lose 2½ times as much as an adult through this route.

Various ideas of causation have been proposed: excess of fat or carbohydrate, parenteral origin, infectious agents, and injudicious use of cathartics. Heubner pointed out its similarity to Asiatic cholera, known to be of an infectious nature.

Therapeutically it is known that if the infant is given food, especially an excess of fat or carbohydrate, the diarrhea becomes worse and that soluble metabolites in the blood increase the osmotic pressure and decrease available water reserve. Thus it is necessary to provide sufficient fluids. It is impossible to accomplish this by oral administration. Ringer's solution or physiologic sodium chloride may be given subcutaneously and a small amount intravenously. However, the most efficient means of introducing water to these infants is by way of the peritoneal cavity as employed extensively by Howland. Alkali administration is unnecessary to correct the acidosis unless of a severe degree, as this disappears when a sufficient amount of fluid is given.

The chronic condition of malnutrition, marasmus, develops insidiously and may accompany various disorders, but the ultimate fate is similar. The infant wastes to a skin-covered skeleton with cold extremities, a slow pulse, and low body temperature. The urine is usually normal but for a higher ammonia coefficient. A negative nitrogen balance exists. The blood volume may be normal, acidosis does not occur, and the circulation is undisturbed. Prolonged underfeeding is the most common cause, and once the condition is fully developed the tolerance for food may be so low that it is impossible to give a sufficient amount to cover even the basal energy requirements. Breast milk appears to be better tolerated and it is thought that the protein of cow's milk may be harmful. These infants need calories, protein, and mineral salts and the necessary accessory substances known as vitamins. Fat is not well tolerated and large amounts of carbohydrate cannot be used without producing irritation of the intestinal tract. Though the therapeutic indications are clear, they are too often difficult or impossible to fulfill.—W. McKim Marriott, Department of Pediatrics, Washington University, and St Louis Children's Hospital, St Louis (20:461-485, December 1920).

PNU Intoxication

Sir.—Drs Johnson, Kubic, and Levitt presented an informative discussion of the toxic condition caused by accidental ingestion of *N*-3-pyridylmethyl *N'-p*-nitrophenyl urea (PNU, Vacor rat killer) (JOURNAL 134:161-164, 1980). Their patient fortunately recovered, as has been the case with several children with PNU intoxication known to me. Because further studies[1-5] of PNU have amplified the clinical and toxicological information presented in this article, I would like to add some comments to their report.

Among adult patients ingesting various doses of PNU, ketosis-prone hyperglycemia, orthostatic hypotension, gastrointestinal hypomotility, and peripheral neuropathy were prominent features in most cases; in some, signs of encephalopathy also developed.[1] Orthostatic hypotension has been the most important lasting disability, whereas some of the other symptoms tended to improve. The neurological and diabetic complications may develop within hours or days after PNU ingestion and may progress in spite of administration of the proposed antidote, niacinamide.

The current understanding of PNU toxicity is more advanced than the authors intimated. Studies of PNU by the manufacturer have investigated the organ disposition,[6] metabolic and pharmacological interactions,[7] and biotransformation (F. W. Deckert, Rohm and Haas Co, personal communication). Of note is the apparent lack of any PNU toxic reaction in primates or several other animal species. It may be misleading to extrapolate from the animal toxic reactions of compounds with some similarity to PNU the situation of human toxic conditions; streptozocin, for example, proves to be a poor rodenticide, whereas PNU does not readily produce diabetes in rats. 6-Aminonicotinamide,[8] a niacinamide antagonist that produces a toxic condition in rodents similar to that produced by PNU, has not produced in experimental human use the spectrum of toxic reactions associated with PNU.[9] Hence, the pharmacological considerations of PNU toxicity are, at this time, largely speculative.

The optimal therapy for PNU poisoning includes the use of parenteral niacinamide, as suggested by animal intoxication data. If niacinamide is not on hand, however, immediate therapy should be undertaken with whatever form of the vitamin is available (such as multivitamin preparations) since the body is capable of interconversion of the various forms of niacin. Attempts at inducing emesis and catharsis, as advocated in the report by Johnson et al, may be ineffective in the face of the ileus and esophageal hypomotility produced by PNU. I would recommmend extensive effort at gastric and enteral drainage to remove any residual toxin. Doses of niacinamide larger and more frequent than what were advised are probably not contraindicated. An additional therapeutic strategy might be beneficial, if I may indulge in some speculative toxicology: 6-aminonicotinamide toxic reaction was reversed in dogs with the use of corticosteroids,[10] and this untested therapy might conceivably be effective in human PNU intoxication. A treatment for the orthostatic hypotension has been previously discussed.[1]

Treatment and Prophylaxis Failure of Erythromycin in Pertussis

Sir.—The report by Halsey and associates (JOURNAL 134:521-522, 1980) deserves critical review. They observed an infant with clinical pertussis, the culture being positive; after only seven days of erythromycin therapy, the infant was found on the eighth day to have a positive culture for *Bordetella pertussis*. The fluorescent antibody (FA) test on the same sample was negative. This does not necessarily indicate an erythromycin treatment failure.

Short courses of erythromycin are often followed by bacteriologic relapse. We observed such a relapse in the first of ten patients treated with erythromycin in our study of pertussis.[1] This patient had negative culture and FA test after 48 hours of treatment. She was treated for ten days, and one day after stopping erythromycin therapy she again had positive culture and FA test; this persisted for four days. We did not (and have not since) observed a bacteriologic relapse in patients treated for 14 days. In the patient described by Halsey et al, the negative FA test on the same specimen that had positive culture suggests a substantial suppressive effect of erythromycin on the organism.

The authors also observed a second infant in whom clinical pertussis with positive culture developed after three days of erythromycin therapy. However, erythromycin was not begun until at least five days after exposure. They interpreted this as a failure of prophylaxis, but this is not a fair test. It more likely represents failure to abort an incubating infection. The mild and short subsequent course of illness suggests that the disease may have been favorably modified. Apparently, pertussis organisms were not recovered from the second patient after the original isolation.

It is unfortunate that the organisms isolated from both patients were lost before antimicrobial sensitivity studies could be performed. To our knowledge, erythromycin-resistant *B pertussis* organisms have not been reported.

We concur that studies evaluating erythromycin prophylaxis against pertussis in susceptible contacts are needed. Passive protection cannot be achieved with pertussis hyperimmune globulin, and no antimicrobial agent has shown as much promise as has erythromycin in preventing or modifying the disease. Until such studies are available, there appears to be enough evidence, adequately referenced in the report of Halsey et al, to continue use of erythromycin in the treatment of pertussis. It will render the cultures of patients negative, and they will be presumably noncontagious. In susceptible patients exposed to persons with pertussis of positive culture, the drug may prevent or clinically modify the disease as well as render the patients' cultures negative and thus help curb spread of the disease in epidemic situations.

Gastroschisis

Sir.—Carlos F. Salinas and associates have reported the occurrence of gastroschisis in siblings (JOURNAL 133:514-517). My experience shows that gastroschisis and omphalocele can occur in siblings and suggests that the former condition also represents anomaly of the umbilical ring.

Report of Cases.—CASE 1.—This male infant was born after a 34-week gestation to a 23-year-old primigravida, para 1 woman and her 18-year-old husband. The infant weighed 2,140 g and had eviscerated, thickened intestines with malrotation, protruding through a 5-cm cleft to the right side of an intact umbilicus. Surgical closure of the defect was performed. He is now 5 years old. We found no history of abdominal-wall defect in the family.

CASE 2.—The boy's sister was a full-term stillborn infant with a huge umbilical omphalocele and no additional anomalies.

Comment.—To our knowledge, familiar occurrence of omphalocele and gastroschisis has not been hitherto reported.

Heart Failure and Cystic Fibrosis

Sir.—Stern et al, in their article "Heart Failure in Cystic Fibrosis" (JOURNAL 134:267-272, 1980), reconfirmed both the dismal outlook for cystic fibrosis (CF) patients in whom overt right-sided heart failure develops and the relative lack of efficacy of digitalis in treating overt failure.[1] However, two questions arise. Fishman[2] has described an escalating continuum of pulmonary hypertension, cor pulmonale (secondary enlargement of the right ventricle), and overt right-sided heart failure. The patients described by Stern et al fall into the last category. Do the authors have data on the efficacy of treatment of patients with pulmonary hypertension or with cor pulmonale without overt right-sided heart failure?

The second question concerns the mixed venous P_{O_2} ($P\bar{v}O_2$) of these patients. Mithoefer et al[3] studied the relationship of arterial blood gases (ABG) to $P\bar{v}O_2$ in 55 adult patients with chronic obstructive lung disease. However, their diagnoses were not specified. They found that the $P\bar{v}O_2$ was fairly predictable on the basis of the ABG. If the $PaCO_2$ was normal (ie, < 44 torr) and the PaO_2 was 63 torr or more, $P\bar{v}O_2$ was normal (≥ 34 torr). In the hypercapnic group ($PaCO_2 > 46$ torr), a lower PaO_2 (50 torr) was the cutoff point for a normal $P\bar{v}O_2$. Estimation of the $P\bar{v}O_2$ is important because it is believed to be a reliable index of tissue P_{O_2}[4] and because in patients with large anatomic shunts, a fall in $P\bar{v}O_2$, per se, may worsen arterial hypoxemia. This is of some interest since the cachexia seen in adolescents and young adults with CF is *not* explained by steatorrhea and azotorrhea but is more closely correlated with the degree of pulmonary disease.[5] If the $P\bar{v}O_2$ reflects tissue P_{O_2}, then the $P\bar{v}O_2$ may be an important factor for prognosis in these patients.

The ABG data of Stern et al would place all of their patients into either of the two low-$P\bar{v}O_2$ categories of Mithoefer et al. Do the authors have data that would confirm the relationship of $P\bar{v}O_2$ to the ABG in patients with CF or that would correlate $P\bar{v}O_2$ with survival?

4. Tenney SM: A theoretical analysis of the relationship between venous blood and mean tissue oxygen pressures. *Respir Physiol* 20:283-290, 1974.
5. Lapey A, Kattwinkel J, diSant'Agnese PA, et al: Steatorrhea and azotorrhea and their relation to growth and nutrition in adolescents and young adults with cystic fibrosis. *J Pediatr* 84:328-334, 1974.

In Reply.—We have no catheterization data on pulmonary hypertension in patients with CF prior to the onset of overt right-sided heart failure and thus are unable to evaluate any treatment measures at this stage of the disease. Long-term controlled studies of many moderately involved patients with CF would be necessary and, to our knowledge, this type of information will not be available for many years.

With regard to the questions concerning $P\bar{v}O_2$, all of our patients had abnormal values (<34 mm Hg) and all

also had arterial Po_2 below 50 mm Hg. In this group, therefore, we are unable to comment on the relationship between a variety of arterial Po_2 values and the $P\bar{v}o_2$. A preliminary examination of $P\bar{v}o_2$ data in our patients (analyzable data are available on 25 of the 31 patients catheterized) does not suggest a clear indication of a relationship with survival. The mean Po_2 for the entire group was 23.7 mm Hg (range, 12 to 33 mm Hg), and the mean Po_2 for the five patients with the longest survival (on whom data are available) was 23.6 mm Hg.

Screening Newborns for Sickle Cell Anemia

Sir.—Rubin and Rowley's article in the JOURNAL (1979;133:1248-1250) and Miller's editorial in the JOURNAL (1979;133:1235-1236) on newborn screening for sickle cell anemia both suggest that in addition to the problems that can arise through difficulty in making a diagnosis of sickle cell disease during the postnatal period, there is the following problem: confusion within the medical profession both as to methods of diagnosis and definition and to the clinical picture of the varying clinical syndromes. β Thalassemia occurs in the following two forms in the black population: β^+, in which varying amounts of hemoglobin (Hb) A are produced, and β°, in which no Hb A is produced. *Both* are characterized by a low mean corpuscular volume (MCV), an elevated Hb A_2 level, and unbalanced α to β synthesis.

As Drs Rubin and Rowley indicate, the clinical picture may vary from a totally benign course to one indistinguishable from Hb SS disease. Current knowledge would suggest that the β^+ form is the most benign. Clinical studies are currently under way that should clarify these syndromes further. But even on the basis of current knowledge, it is probably essential to be certain to designate whether the β thalassemia under discussion is of the A- (β^+) or non-A (β°)-producing type. This the authors fail to do in their rather confusing discussion of the clinical syndrome or syndromes.

Hemoglobin S/hereditary persistence of fetal hemoglobin (HPFH) is a rare syndrome that (to my knowledge) has to date only been described as a totally benign laboratory finding with no anemia and no changes in the MCV. As more clinical cases are described, whether the clinical picture will continue to be consistently benign remains to be seen. It should also be noted that there have been recent reports of HPFH trait occurring in blacks where the distribution of Hb F is not homogeneous.

The complexities of accurate hemoglobin genotype diagnosis are further confused by several statements in Dr Miller's editorial. It is not true that "citrate agar gel electrophoresis at a pH of 6.2 will permit differentiation of sickle cell anemia from Hb S/HPFH and Hb S/β-thalassemia." The presence of an A_2 band will suggest that the patient has a β thalassemia gene, but no further information is gained about the nature of the F band. Such information can only be gained by procedures such as the Kleihauer-Betke stain, and perhaps more importantly from family studies. This is particularly true in the postnatal period, when Hb F levels are uniformly high and accurate diagnosis is needed.

Family studies are key. It is inconceivable that any properly trained, responsible physician would attempt to counsel a family about any genetic disorder without first attempting to screen the parents. (At different times in the clinical course of the infant as described, the mother could have had any one of the following genotypes: AS, SS, Aβ^+ thalassemia, Hb A/HPFH, Sβ^+ thalassemia, Hb S/HPFH, β^+ thalassemia/HPFH, and possibly others.) How else can the family be given accurate information?

Dr Miller has missed the point. The inaccuracy of a presumptive diagnosis by the New York State Screening Laboratory should not be allowed to obscure the inadequacies of resources for follow-up through parental testing; neither does the general medical community appear to be well enough educated to answer this role. It is hoped that through the recent acquisition of additional federal funding for education, screening, and counseling this distressing situation will change.

JEANNE A. SMITH, MD
Comprehensive Sickle Cell Center
Harlem Hospital Center—
Columbia University
Suite 6146
135th Street and Lenox Avenue
New York, NY 10037

Sir.—We read with interest the report by Drs Rubin and Rowley and the editorial by Dr Miller in the JOURNAL (1979;133:1248-1250 and 1235-1236). There is an apparent misunderstanding about the procedures used to identify newborns with sickle cell anemia and its variants in the New York State Newborn Screening Laboratories. In the presence of Hb S or Hb C on the filter paper blood specimen tested by both cellulose acetate and citrate agar electrophoresis, a repeat blood sample is requested. The repeat specimen (microcapillary) is again tested by both types of electrophoresis before the result is mailed to the physician in charge of the infant in the hospital of birth.

It is unfortunate that citrate agar electrophoresis cannot distinguish between Hb SS, S/β° thalassemia, and Hb S/HPFH, as has been suggested by Dr Miller in his editorial. The Newborn Screening Laboratories are equipped to make diagnoses of Hb SC, Hb SD, Hb SS, Hb AS, Hb AC, and other rare hemoglobinopathies.

According to the guidelines set by the State Commissioner of Health, the results of sickle cell testing are mailed by the Newborn Screening Laboratory to the hospital where the infant was born. The correspondence should clearly state that results are obtained through *screening* tests and place the responsibility for the definitive diagnosis with the physician who will be following up the child.

Since the diagnosis of Hb S/HPFH cannot be made from the infant's blood at birth, the diagnosis is made in later infancy on clinical grounds (ie, the benign course of the condition) and by laboratory data through absence of evidence of hemolysis, the presence of Hb S but no Hb A on electrophoresis, a high Hb F level (15% to 35%), and the demonstration of a uniform distribution of Hb F in a blood smear stained by Kleihauer-Betke stain. The diagnosis can be made at birth if both parents are available for testing and if the test

results show one to have HPFH and the other to have Hb AS. In the family of reference, neither confirmatory testing nor family studies were obtained appropriately on first hospitalization.

The frequency of HbS/HPFH is expected to be very low[1] despite the figures found in the series reported by Kramer et al.[2] However, there will be a rare "benign positive" case referred to as SS, resulting in unnecessary anxiety to the parents. The physician following up the infant must make the definitive diagnosis accurately and expeditiously and reassure the parents if the original diagnosis was erroneous.

Sir.—The report of Rubin and Rowley and the accompanying editorial concerning Hb S and HPFH in a newborn was of interest to us (JOURNAL 1979;133:1248-1250 and 1235-1236). We have recently found a similar patient in our newborn screening program. However, we take exception to the statement that acid agar electrophoresis permits differentiation of sickle cell disease from Hb S/HPFH and Hb S/β thalassemia. The agar adds nothing to the differential diagnosis. As indicated by Rubin and Rowley, differentiation requires family study and/or other methods for establishment of the genetic basis for the Hb FS phenotype. We are also confused by the final comment in the editorial about the low incidence of sickle cell anemia in patients without Hb A.

JAMES C. DETTER, MD
JUDITH A. JONES
CAROL N. LECRONE, MS
Department of Laboratory Medicine
University of Washington
Seattle, WA 98195

Sir.—I want to make a brief comment about the statement that citrate agar electrophoresis at a pH of 6.2 will permit differentiation of sickle cell anemia from Hb S/HPFH and Hb S/β thalassemia that appeared in the editorial by Miller in the December 1979 issue of the JOURNAL (1979;133:1235-1236).

Citrate agar electrophoresis at an acid pH may permit the clear recognition of small amounts of Hb A and Hb S in cord blood and aid in the diagnosis of sickle-β^+ thalassemia. However, citrate agar electrophoresis (in cases with an absence of Hb A) will not permit the differentiation of homozygous sickle hemoglobinopathy from sickle-β° thalassemia, sickle-β°/HPFH, and sickle-$\delta\beta$ thalassemia. The differentiation of homozygous sickle hemoglobinopathy from these syndromes may require other studies, including the quantitation of Hb F and Hb A_2, Kleihauer-Betke staining for the study of distribution of Hb F, hematological evaluation (complete blood cell count, smear evaluation, and irreversible sickle cells), in vitro globin-chain synthetic ratio determination, and family studies. While the value of these tests in sorting out some of the sickle syndromes involving the β globin locus in the adult is reasonably understood, they may be of little value in the newborn. As pointed out in the editorial, family studies, when available, are clearly valuable in this setting.

KODURI R. P. RAO, MD
Division of Hematology
Cook County Hospital
1826 W Harrison St
Chicago, IL 60612

In Reply.—Dr Smith would have preferred that our differential diagnosis of the proposita deal more extensively with β^+ vs β° thalassemia and the difference in their clinical presentation. We point out that the differential diagnostic process for newborns differs from that appropriate for the symptomatic child in that there is no clinical history. The differential diagnosis is that of a hemoglobin composition, not that of a clinical course. The hemoglobin composition of the proposita described (principally Hb S without Hb A) automatically excludes sickle-β^+ thalassemia, and therefore it was not discussed. As explained in the third paragraph of the "Comment" section, it is sickle-β° thalassemia that must be distinguished from sickle cell anemia because in both there is no synthesis of Hb A.

Drs Grover and Wethers claim that, in the family described, "neither confirmatory testing nor family studies were obtained appropriately." Regarding confirmatory testing, as the article states,

> The presence of an unusually high level of fetal hemoglobin past the neonatal period, the absence of sickle hemoglobin in one parent, the even distribution of Hb F among the RBCs, and the balanced synthesis of α and non-α globin chains, all of which were demonstrated in the twins reported here, confirm the diagnosis.

Regarding family studies, the data supporting the diagnosis of HPFH trait in the mother was presented and was essential to establish the diagnosis of sickle cell trait/HPFH trait in the proposita. Indeed, the family illustrates the fact that in cases where one parent is not available, as we described to be the case here, finding no Hb S in one parent suffices to rule out homozygous Hb S disease in the child.

Dr Smith states, "It is inconceivable that any properly trained, responsible physician would attempt to counsel a family about any genetic disorder without first attempting to screen the parents." We agree that parental testing is an essential part of the diagnosis of sickle cell anemia. However, physicians in our area who receive reports of sickle cell disease in a child under their care are generally not testing parents. We have learned this from our follow-up study of the first 25 cases of sickling hemoglobinopathies diagnosed by state-mandated newborn screening in western New York State.

There are two ways to remedy the current lack of parental testing. The one advocated by Drs Grover and Wethers is for the state's report to the physician to clearly indicate that the result is presumptive and that definitive diagnosis is the responsibility of the physician. The second, which is proposed by us in the article's penultimate paragraph, is for the state, when requesting a second blood sample from the child, to require samples from the parents as well. We do not oppose educating physicians; in fact, we devote much of our time to this activity. However, we believe that the

state, which is providing a medical service that the family has not requested, has the responsibility to protect the family against the false diagnosis of a disease that is often fatal in early childhood. The unfortunate consequences of the latter are illustrated by the family described. Testing of the parents by the state at the time of confirmatory testing of the infant may help avoid the parental anxiety that Drs Grover and Wethers aptly term "unnecessary."

Dr Rubin is now with the University of California at San Francisco.

1. Steinberg WN, Humbert J, Rowley PT: Impact of diagnosis of sickle cell disease at birth on physicians and on parents, abstracted. *Am J Hum Genet* 1979;31:126A.

In Reply.—Dr Smith, Drs Grover and Wethers, Dr Detter and colleagues, and Dr Rao have correctly emphasized that citrate agar electrophoresis at an acid pH will not differentiate homozygous sickle cell anemia from sickle cell variants associated with thalassemia syndromes and HPFH. It will facilitate the detection of small amounts of Hb A and clearly separate Hb F from Hb S.[1] On that point I stand corrected.

As stated in the editorial (JOURNAL 1979;133:1235-1236) and as presented in the article by Rubin and Rowley (JOURNAL 1979;133:1248-1250), additional laboratory studies on the newborn and on family members are absolutely mandatory before a definitive diagnosis of homozygous sickle cell anemia can be made. My concerns are with the responsibilities of the state screening programs. What will the pediatrician do with information provided by repeated testing that confirms the original result of "consistent with sickle cell anemia"? This is the problem. To avoid misdiagnosis and the attendant emotional trauma to the family, responsible state screening programs, in confirming the absence of Hb A, should recognize the alternative diagnoses (sickle cell trait/HPFH, sickle cell trait/β^+ thalassemia, sickle cell trait/β° thalassemia, and sickle cell/Hb D disease) and clearly instruct the pediatrician that additional studies are mandatory before a definitive diagnosis of sickle cell disease can or should be made. To avoid recurrences, the state laboratory should add an educational function to its existing screening program. With clearer guidelines and suggestions from the screening program (eg, hematology consultation, with additional laboratory and family studies) the practitioner can proceed logically before acting on inaccurate laboratory reports and treating when there is no disease.

Prune-Belly Syndrome

Sir.—The article by Siebert entitled "Small-Intestine Length in Infants and Children" (JOURNAL 1980;134:593-595) reports one instance of an intra-abdominal lesion in which the small-intestinal length was greater than 2 SDs from the expected mean length. This was in an infant with the prune-belly syndrome in whom the expected small-intestinal length was 164 ± 54 cm (1 SD) and the observed length was 294 cm, greater than 2.4 SDs from the expected mean. One possible explanation for this observation is that linear growth of the small intestine is, in part, determined by the tension on it and the space available for it. When there is lax or absent abdominal wall musculature, as in the prune-belly syndrome, there will be greater intra-abdominal volume and thus additional growth of the small intestine can be accommodated. A similar explanation has been suggested as the basis of linear growth of another tube-like structure, the umbilical cord.[1]

MARVIN MILLER, MD
University of Washington
Medical Genetics
Seattle, WA 98195

1. Miller ME, Higginbottom MC, Smith DW: Intrauterine constraint as a cause of short umbilical cord, abstracted. *Pediatr Res* 1980;14:586.

In Reply.—I thank Dr Miller for his interesting comments on elongation of the small intestine in the prune-belly, or abdominal muscular deficiency, syndrome. There are additional data with regard to small-intestinal length with which one may study the possible effect of constraint on developing tissues. In six infants with congenital diaphragmatic hernia, the mean small-intestinal length was 39 cm shorter than normal, although within 1 SD. In two cases of omphalocele, the mean small-intestinal length was decreased by 76 cm, beyond 1 SD. Likely reasons for this tendency toward abnormal shortening seem to conflict, however. If the pleural space in diaphragmatic hernia or the omphalocele sac serve as extensions of the abdominal cavity, then there seems to be increased space in which the small intestine can develop. In this instance, one might expect elongation of the small intestine to occur, vis-à-vis the Miller hypothesis. Conversely, in the two malformations, varying lengths of intestine are sometimes encountered within the pleural cavity or omphalocele sac, rather than in the abdominal cavity per se. These secondary cavities are considerably smaller than the usual peritoneal space and possibly produce a degree of constraint on the growing intestine. The constriction, if it occurs, must be mild, for changes due to severe hypoxia, torsion, or incarceration are generally not seen in the intestinal tract and symptoms are primarily respiratory ones in infancy.[1] Shortening is probably not due to deficient mesenteric attachments, for the mean small-intestinal length in eight cases of isolated malrotation was mildly elongated, but well within 1 SD. Whether two populations exist, ie, those intestinal tracts that develop within extended abdominal cavities and those constrained by ectopic ones, is not known presently.

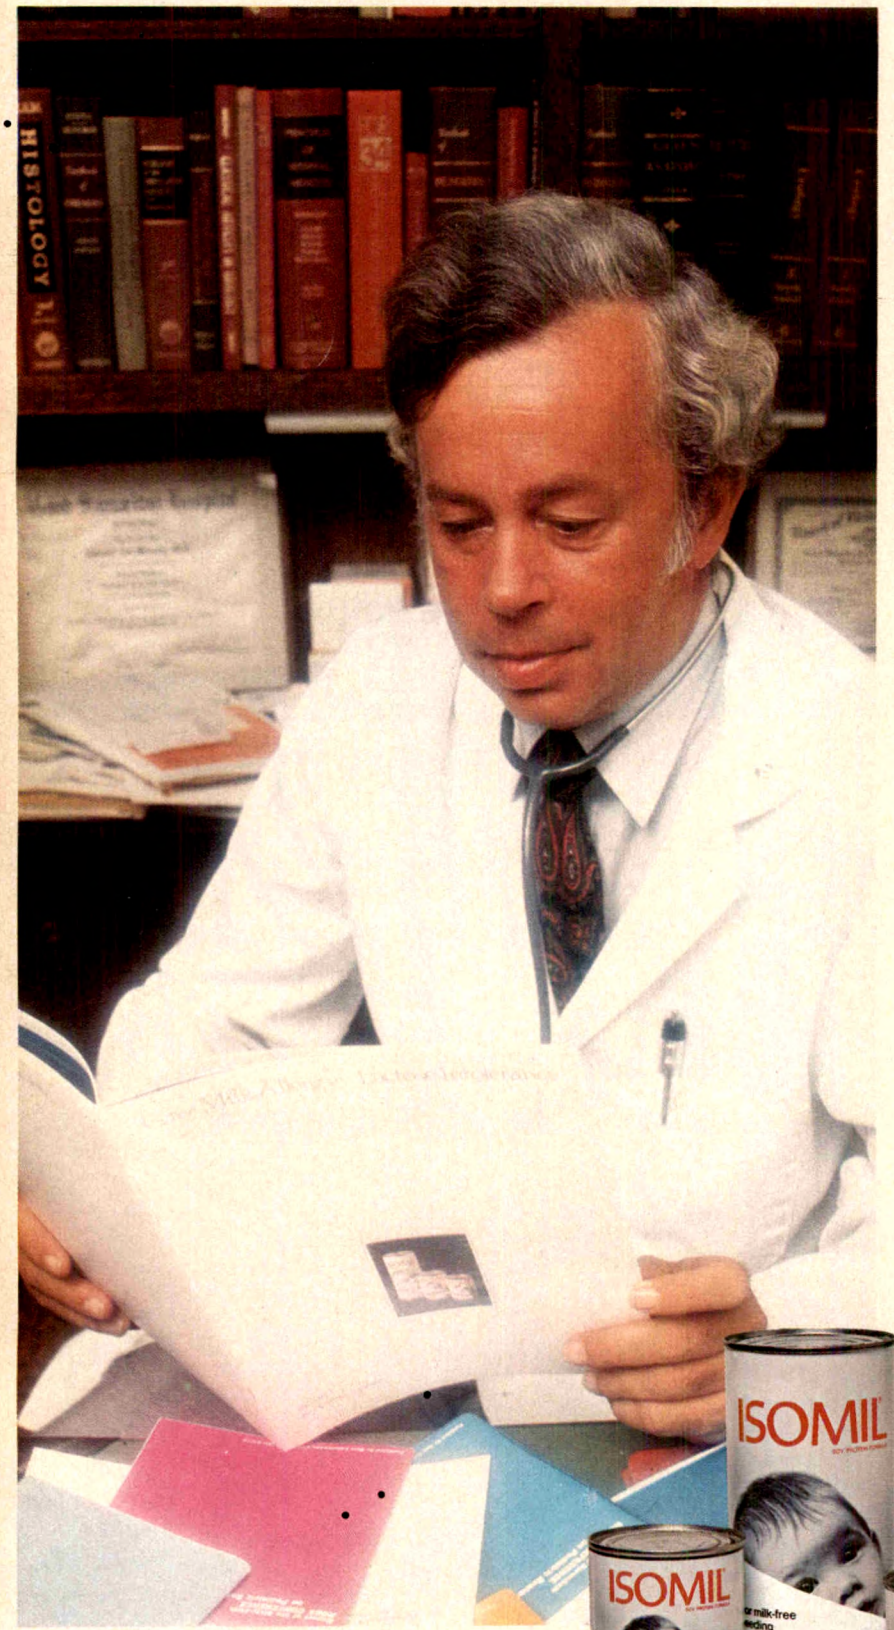
Clinical research is our tradition



What does a tradition of clinical research mean to you? Simply, it means you can recommend Isomil® Soy Protein Formula with confidence that your patients' nutritional needs will be met. One study, for example, documented that infants will grow as rapidly when fed Isomil as those infants fed a cow milk formula.[1] A second study confirmed these findings.[2]

Isomil was also found effective in preventing recurrence of diarrhea due to secondary lactose intolerance. One clinical study found that diarrhea recurrence rates were lower with the group fed Isomil than those fed a milk-based formula.[3] Another study confirmed these findings.[4]

These are four of the studies that have been conducted with Isomil. Clinical research is one reason you can recommend Isomil with confidence: for the infant with a sensitivity to cow milk or with secondary lactose intolerance.

SUBJECT INDEX TO VOLUME 134

The following Index is an alphabetical list of significant subjects presented in this volume. Books reviewed are listed alphabetically by first author under the heading "BOOK REVIEWS."

A

Abdomen
computerized tomography in diagnosis of cerebellar ataxia, opsoclonus, and occult neural crest tumor [Kinast] 1057 (No)
pancuronium and abnormal abdominal roentgenograms [Dillard] 821 (Se)

Abdomen, Acute
pulmonary veno-occlusive disease appearing as acute, recurrent abdominal pain (clin. memo.) [Weinberg] 86 (Ja)
recurrent abdominal pain (letter) [Crook] 326, (reply) [Stickler] 327 (Mr)
recurrent abdominal pain in childhood [Lebenthal] 347 (Ap), (letter) [Rapp] 998 (Oc)

Abdominal Neoplasms
vasoactive intestinal peptide secreting tumors of childhood [Kaplan] 21 (Ja)

Abdominal Wall
association of 'prune belly' with Turner's syndrome (clin. memo.) [Lubinsky] 1171 (De)
gastroschisis, anomaly of umbilical ring as factor in (letter) [Gaillard] 1179 (De)
necrotizing fasciitis after neonatal circumcision [Woodside] 301 (Mr), (letter) [Katz] (reply) [Woodside] 1098 (No)
prune-belly syndrome, small intestine elongated in (letter) [Miller] (reply) [Siebert] 1182 (De)

Abnormalities
great expectations (letter from abroad) [Barrie] 901 (Se)
intrathoracic rib, radiological case of month [Young, Hilton] 1085 (No)
live-born triploid (clin. memo.) [Fraikor] 988 (Oc)
ring chromosome 15 and failure to thrive (clin. memo.) [Kousseff] 798 (Au)

Abnormalities, Drug-Induced
Ebstein's anomaly of tricuspid valve associated with prenatal exposure to lithium carbonate (clin. memo.) [Park] 703 (Jy)
fetal damage due to aminopterin ingestion, follow-up at 17½ years of age (clin. memo.) [Shaw] 1172 (De)

Abnormalities, Multiple
campomelic dysplasia, further elucidation of distinct entity [Hall] 285 (Mr)
case of leprechaunism with severe hyperinsulinemia [Rosenberg] 170 (Fe)
cleidocranial dysostosis, severe micrognathism, bilateral absence of thumbs and first metatarsal bone, and distal aphalangia, new genetic syndrome [Yunis] 649 (Jy)
craniosynostosis-radial aplasia, Baller-Gerold syndrome (clin. memo.) **133:**1279 (De), correction, **134:**363 (Ap)
lip pits, cleft lip and/or palate, and congenital heart disease [Pauli] 293 (Mr)
malformation complex, spondylohypoplasia, arthrogryposis, and popliteal pterygium [Turkel] 42 (Ja), (letter) [Torres-Aybar] 1001 (Oc)
Marden-Walker syndrome (letter) [Fitch] 93 (Ja)
partial trisomy 9q due to maternal 9/17 translocation [Aftimos] 848 (Se)
Rothmund-Thomson syndrome with severe dwarfism [Hall] 165 (Fe)
syndrome of infantile CNS degeneration [Holmes] 262 (Mr)

Abscess
pilonidal cyst, in children, aerobic and anaerobic bacteriology of [Brook] 679 (Jy)

Absorption, Intestinal see Intestinal Absorption

Accidents
accidental ingestion of Vacor rodenticide, (PNU), symptoms and sequelae [Johnson] 161 (Fe), (letter) [LeWitt] 1178 (De)
acute iron poisoning, review [Robotham] 875 (Se)

Acedapsone see Dapsone

Acetaminophen
epidemiology of poisoning from drug products [Saracino] 763 (Au)

Acetone Bodies see Ketone Bodies

Acetylsalicylic Acid see Aspirin

Achievement
5-hydroxytryptophan and pyridoxine, effects in young children with Down's syndrome [Pueschel] 838 (Se)

Acrocephaly see Craniosynostoses

Acrodermatitis Enteropathica
essential fatty acids revisited [Friedman] 397 (Ap)

Acrodynia
polyneuritic syndrome resembling pellagra-acrodynia (?) seen in very young children, *60 Years Ago in AJDC*, 1064 (No)

ACTH see Corticotropin

Adenoma
unilateral thyroid enlargement with hyperthyroidism (clin. memo.) [Leung] 890 (Se)

Adenomatosis, Familial Endocrine
functioning tumors [Voorhess] 14 (Ja)

Adenosine Deaminase
partial resolution of bone lesions, child with severe combined immunodeficiency disease and deficiency of, after enzyme-replacement therapy [Yulish] 61 (Ja)

Adolescence
bilateral carpal tunnel syndrome in adolescent [Feingold] 394 (Ap)
condoms for sexually active adolescents [Bergman] 247 (Mr); advertising condoms (letters) [Friday, Feroli] (reply) [Bergman] 1000 (Oc)
diets for children and adolescents that meet dietary goals [Dwyer] 1073 (No)
impact of mass media on adolescent sexual behavior, chicken or egg? [Hein] 133 (Fe)
psychological factors in diabetes mellitus (letter) [Laron] (reply) [Greydanus] 1004 (Oc)

Adrenal Cortex Hormones
plasma adrenocorticotrophic hormone in congenital adrenal hyperplasia, importance in long-term management [LaFranchi] 1068 (No)

Adrenal Gland Hyperfunction
plasma adrenocorticotrophic hormone in congenital adrenal hyperplasia, importance in long-term management [LaFranchi] 1068 (No)

Adrenal Gland Neoplasms
functioning tumors [Voorhess] 14 (Ja)

Adrenergic Beta Receptor Agonists
management of acute asthma in childhood, randomized evaluation of [Schwartz] 474 (My)

Adrenocorticotrophic Hormone see Corticotropin

Advertising
condoms (letters) [Friday, Feroli] (reply) [Bergman] 1000 (Oc)
drug, in *ADJC* (letter) [Barna] (reply) [Barclay] 902 (Se)

AFP see Alpha Fetoproteins

Agammaglobulinemia
immunologic maturation in infant born to mother with [Kobayashi] 942 (Oc)
pneumatosis intestinalis, occurrence in immunologically compromised child [Kleinman] 1149 (De)

Agranulocytosis
Staphylococcus aureus sepsis in childhood malignancy [Miser] 831 (Se)
transient "lazy-leukocyte" syndrome during infancy [Yoda] 467 (My)

Airway Obstruction
migration of inflorescence, complications of grass head aspiration (clin. memo.) [Steele] 704 (Jy)

Alcohol, Ethyl
neonatal death associated with acute transplacental ethanol intoxication (clin. memo.) [Jung] 419 (Ap)

Alcohol, Propyl
epidemiology of poisoning from drug products [Saracino] 763 (Au)

Alcoholic Beverages
neonatal death associated with acute transplacental ethanol intoxication (clin. memo.) [Jung] 419 (Ap)

Aldosteronism see Hyperaldosteronism

Alkaline Phosphatase
serum levels, asymptomatic familial elevation of (clin. memo.) [Parker] 1094 (No)

Alpha 1-Antitrypsin
infantile cholestatic liver disease (letters) [Harris] 623 (Je), 801 (Au), (reply) [Rosenthal] 802 (Au)

Alpha Fetoproteins
increased amniotic fluid α-fetoprotein, familial hydrocephalus, and renal dysmorphology (clin. memo.) [Sinclair-Smith] 619 (Je)

Altitude Sickness see Anoxia

Amantadine
for severe influenza A pneumonia in infancy (clin. memo.) [Fishaut] 321 (Mr)

Ambulatory Care
pediatrics and record-keeping (letter) [Sparling] (reply) [Margolis] 326 (Mr)

American Journal of Diseases of Children
drug advertising (letter) [Barna] (reply) [Barclay] 902 (Se)
Honor Roll of reviewers for 1979, 85 (Ja)

6-Aminonicotinamide see Nicotinamide

Aminophylline
intravenous, in cystic fibrosis, pharmacokinetics and effect on pulmonary function [Larsen] 1143 (De)
intravenous therapy for asthma, comparison of 2 methods of administration [Goldberg] 596 (Je)

Aminopterin
fetal damage due to ingestion of, follow-up at 17½ years of age (clin. memo.) [Shaw] 1172 (De)

Amniotic Fluid
increased α-fetoprotein, familial hydrocephalus, and renal dysmorphology (clin. memo.) [Sinclair-Smith] 619 (Je)

Amoxicillin Trihydrate
cefaclor in treatment of otitis media and pharyngitis in children compared with [McLinn] 560 (Je)

Amphotericin B
aspergillosis in chronic granulomatous disease, therapeutic considerations (clin. memo.) [Corrado] 1092 (No)

Amyoplasia Congenita see Arthrogryposis

Anaphylaxis
eye involvement in anaphylactoid purpura (clin. memo.) [Lorentz] 524 (My)

Androgens
phenotypic variation in family with partial androgen insensitivity syndrome [Maes] 470 (My)

Anemia
pure red cell, and macrocytosis caused by azathioprine [DeClerck] 377 (Ap)
vitamin E and neonate [Ehrenkranz] 1157 (De)
Anemia, Hemolytic
microangiopathic, simultaneous thrombocytopenia, acute nephropathy and, in mother and child (clin. memo.) [Siegler] 991 (Oc)
Anemia, Sickle Cell
screening newborns for (letters) [Smith, Grover] 1180, [Detter, Rao] 1181, (replies) [Rubin] 1181, [Miller] 1182 (De)
Angina Pectoris
metastatic complications of *Fusobacterium necrophorum* sepsis, 2 cases of Lemierre's postanginal septicemia [Vogel] 356 (Ap)
Angiohemophilia see von Willebrand's Disease
Angiotensin II
Bartter's syndrome (letter) [Sann] (reply) [Arbus] 1097 (No)
Ankyloblepharon Filiforme Adnatum
congenital eyelid-band syndromes [Rosenman] 751 (Au)
Anoxemia
sleep hypoxemia in patients with cystic fibrosis [Mansell] 733 (Au)
sleep hypoxemia in young adults with cystic fibrosis [Stokes] 741 (Au)
Anoxia
heart failure in cystic fibrosis, treatment and prognosis of cor pulmonale with failure of right side of heart [Stern] 267 (Mr), (letter) [Marino] (reply) [Stern] 1179 (De)
hemoglobin desaturation, occurrence during sleep in cystic fibrosis [Francis] 734 (Au)
role of respiratory infection in intrathoracic petechiae, implications for sudden infant death [Guntheroth] 364 (Ap)
Antibiotics
pneumococcal empyema, outcome of medical management [Murphy] 659 (Jy)
streptococci resistant to (letter) [Gentry] 801 (Au)
Antibodies
idiopathic thrombocytopenic purpura (ITP) (letter) [Özsoylu] 93 (Ja)
local immunity in mumps meningitis [Morishima] 1060 (No)
measles-specific lymphocyte reactivity and serum antibody in subjects with different measles histories [Krause] 567 (Je)
Antibody Deficiency Syndrome see Immunologic Deficiency Syndromes
Anticoagulants
corpus luteum hemorrhagicum, unusual complication of therapy with (clin. memo.) [Shapiro] 523 (My)
Antidiuretic Hormone, Inappropriate Secretion see Inappropriate ADH Syndrome
Antidotes
phosphate poisoning complicating treatment for iron ingestion [Geffner] 509 (My)
Antigens
group B streptococcal disease, diagnosis with use of antigen detection, Gram's stain, and presence of apnea, hypotension [Ingram] 754 (Au)
Toxocara, mitogenic response to, and chemotactic defect in visceral larva migrans [Caldwell] 845 (Se)
Antineoplastic Agents
pneumonia during therapy for childhood acute lymphoblastic leukemia [Siegel] 28 (Ja)
Aortic Coarctation
in children, late results after surgery [Beerman] 464 (My)
Apnea
group B streptococcal disease, diagnosis with use of antigen detection, Gram's stain, and presence of hypotension and [Ingram] 754 (Au)
hemoglobin desaturation, occurrence during
Apnea—Continued
sleep in cystic fibrosis [Francis] 734 (Au)
sleep hypoxemia in patients with cystic fibrosis [Mansell] 733 (Au)
sleep hypoxemia in young adults with cystic fibrosis [Stokes] 741 (Au)
Apparatus and Instruments see Equipment and Supplies
Arginine
argininosuccinicaciduria, hair abnormality revisited (clin. memo.) [Potter] 1095 (No)
Argininosuccinic Acid see Arginine
Arm
Hodgkin's disease as epitrochlear adenopathy (clin. memo.) [Berman] 319 (Mr)
Armstrong, George, Award Lecture
are we in midst of a revolution? [Kennell] 303 (Mr)
Arthritis, Juvenile Rheumatoid
diabetes mellitus, Hashimoto's thyroiditis, and (letter) [Fisher] 93 (Ja)
new thoughts on aspirin [Baum] 455 (My)
salicylate therapy in, dose, serum level, and toxicity [Doughty] 461 (My)
Arthritis, Rheumatoid
seropositive, in patient with cystic fibrosis (clin. memo.) [Sagransky] 319 (Mr)
Arthrogryposis
malformation complex, spondylohypoplasia, popliteal pterygium and [Turkel] 42 (Ja), (letter) [Torres-Aybar] 1001 (Oc)
Arthromyodysplasia, Congenital see Arthrogryposis
Ascariasis
human toxocariasis in rural community [Jones] 967 (Oc)
Ascorbic Acid
CSF neurotransmitter studies, infant with tyrosinemia responsive to [Stoerner] 492 (My)
Aspartate Aminotransferase
salicylate therapy in juvenile rheumatoid arthritis, dose, serum level, and toxicity [Doughty] 461 (My)
Aspergillosis
in chronic granulomatous disease, therapeutic considerations (clin. memo.) [Corrado] 1092 (No)
Asphyxia Neonatorum
acute caffeine overdose in neonate [Banner] 495 (My)
intracranial hemorrhage in premature, predictive features and outcome [Kosmetatos] 855 (Se)
Aspiration Biopsy see Biopsy, Needle
Aspiration, Mechanical see Suction
Aspiration Pneumonia see Pneumonia, Aspiration
Aspirin
epidemiology of poisoning from drug products [Saracino] 763 (Au)
new thoughts on [Baum] 455 (My)
salicylate therapy in juvenile rheumatoid arthritis, dose, serum level, and toxicity [Doughty] 461 (My)
Asthma
acute, management in childhood, randomized evaluation of β-adrenergic agents [Schwartz] 474 (My)
intravenous aminophylline therapy for, comparison of 2 methods of administration in children [Goldberg] 596 (Je)
Ataxia, Cerebellar see Cerebellar Ataxia
Athetosis
syndrome of infantile CNS degeneration [Holmes] 262 (Mr)
Athletic Injuries
in high school physical education classes [Austin] 456 (My)
Atrophy
dextrose tolerance in atrophic infants, *60 Years Ago in AJDC*, 45 (Ja)
Atrophy—Continued
Rothmund-Thomson syndrome with severe dwarfism [Hall] 165 (Fe)
Autism
pregnancy, delivery, and neonatal complications among autistic children [Deykin] 860 (Se)
Autoantibodies
infectious mononucleosis initially seen as cold-induced acrocyanosis, association with auto-anti-M and anti-I antibodies [Dickerman] 159 (Fe)
Autoimmune Diseases
thyroiditis with thyrotoxicosis eventuating in short interval hypothyroidism (clin. memo.) [Hahm] 206 (Fe)
Avery, Oswald T. (1877-1955)
lesson in nutrition [Dubos] 583 (Je)
Azathioprine
macrocytosis and pure RBC anemia caused by [DeClerck] 377 (Ap)
Azotemia see Uremia

B

Bacteremia see Septicemia
Bacteria
aerobic and anaerobic bacteriology of pilonidal cyst abscess in children [Brook] 679 (Jy)
anaerobic bacteremia in children [Brook] 1052 (No)
chronic otitis media in children, microbiological studies [Brook] 564 (Je)
disparate cultures of middle ear fluids, results from children with bilateral otitis media [Pelton] 951 (Oc)
Bacterial Infections
immunizations against, review [Harrison] 184 (Fe)
Bacteriophages
nosocomial transmission of bacteriophage type 7/11/12 group B streptococci in special care nursery [Boyer] 964 (Oc)
Bacteriuria
urinary infection in infants and preschool children, 5-year follow-up [Siegel] 369 (Ap)
Bacteroides
chronic otitis media in children, microbiological studies [Brook] 564 (Je)
Baller-Gerold Syndrome
craniosynostosis-radial aplasia (clin. memo.) **133**:1279 (De), correction, **134**:363 (Ap)
Bartlett, Mrs. N. Gray
'Mother Goose of '93,' photograph by 1166 (De)
Bartter's Disease see Hyperaldosteronism
Basedow's Disease see Goiter, Exophthalmic
Battered Child Syndrome see Child Abuse
Beta Adrenergic Receptor Agonists see Adrenergic Beta Receptor Agonists
Beta Cells
insulin biosynthesis and C-peptide, practical applications from basic research [Sperling] 1119 (De)
urine C-peptide, β-cell function, and insulin requirement [Rappaport] 1129 (De)
Beta Lipoproteins see Lipoproteins, LDL
Bile Duct Obstruction see Cholestasis
Bile Ducts
acquired stricture in childhood related to blunt trauma, case report, literature review [Kendall] 851 (Se)
Biliary Calculi see Cholelithiasis
Biliary Stasis see Cholestasis
Biopsy
open lung, congenital miliary tuberculosis proved by, and successfully treated (clin. memo.) [Stallworth] 320 (Mr)
Biopsy, Needle
herpes simplex infection after needle aspiration of lymph node (clin. memo.) [Vikelidou] 88 (Ja)
Birth Weight see Infant, Low Birth Weight

Blepharoptosis
Marcus Gunn phenomenon, picture of month [Gellis, Eckerd] 783 (Au)
Blood
diphtheroid sepsis in child with no predisposing condition (clin. memo.) [MacDonald] 708 (Jy)
immunoglobulin concentrations in duodenal fluid of infants and children [Lebenthal] 834 (Se)
nonketotic hyperglycinemia, effects of therapy with strychnine [Warburton] 273 (Mr)
serum 1,25-dihydroxyvitamin D levels in normal children and in vitamin D disorders [Chesney] 135 (Fe)
Blood Gas Analysis
heart failure in cystic fibrosis, treatment and prognosis of cor pulmonale with failure of right side of heart [Stern] 267 (Mr), (letter) [Marino] (reply) [Stern] 1179 (De)
Blood Glucose see Hyperglycemia; Hypoglycemia
Blood Platelets
essential fatty acids revisited [Friedman] 397 (Ap)
idiopathic thrombocytopenic purpura (ITP) (letter) [Özsoylu] 93 (Ja)
prostaglandins [Olley] 688 (Jy)
spontaneous splenic rupture in acute lymphoblastic leukemia, successful nonoperative management (clin. memo.) [Soorya] 201 (Fe)
Blood Pressure
heart failure in cystic fibrosis, treatment and prognosis of cor pulmonale with failure of right side of heart [Stern] 267 (Mr), (letter) [Marino] (reply) [Stern] 1179 (De)
Blood Pressure, High see Hypertension
Blood Pressure, Low see Hypotension
Blood Transfusion
partial resolution of bone lesions, child with severe combined immunodeficiency disease and adenosine deaminase deficiency after enzyme-replacement therapy [Yulish] 61 (Ja)
spontaneous splenic rupture of acute lymphoblastic leukemia, successful nonoperative management (clin. memo.) [Soorya] 201 (Fe)
Blood Vessels
prostaglandins [Olley] 688 (Jy)
Blunt Injuries see Wounds, Nonpenetrating
Bone and Bones
falsely normal radionuclide scans for osteomyelitis [Fleisher] 499 (My)
long-limbed campomelic dwarfism, radiologic and pathologic study [Austin] 1035 (No)
'normal' technetium bone scans in patients with acute osteomyelitis [Berkowitz] 828 (Se)
Bone Diseases, Developmental
partial resolution of bone lesions, child with severe combined immunodeficiency disease and adenosine deaminase deficiency after enzyme-replacement therapy [Yulish] 61 (Ja)
Bone Dysplasias see Bone Diseases, Developmental
Bone Neoplasms
progressive facial hemiatrophy associated with Ewing's sarcoma [Paradise] 1065 (No)
Bone Resorption
traumatic ischial apophyseolysis, radiological case of month [Young, Tan] 885 (Se)

Brachial Plexus
neuropathy [Charles] 299 (Mr), (letter) [Bale] 903 (Se)
Bradycardia
and hypoglycemia evoke doctrine of *primum non nocere*, is propranolol alone really beneficial in neonatal thyrotoxicosis? [Gardner] 819 (Se)
Brain
computerized tomography to define CNS involvement in congenital cytomegalovirus infection (clin. memo.) [Anders] 795 (Au)
focal cerebral atrophy in incontinentia pigmenti achromians (clin. memo.) [Donat] 709 (Jy)
Brain Diseases
encephalopathy in young children with moderate chronic renal failure [Bale] 581 (Je)
Brain Dysfunction, Minimal see Minimal Brain Dysfunction
Brain Neoplasms
computerized tomography in evaluation of isosexual precocity [Hung] 25 (Ja), (letter) [Schwartz] 802 (Au)
intracranial dermoid cyst, diagnosis of computer-

Brain Neoplasms—Continued
ized tomography (clin. memo.) [Maulsby] 420 (Ap)
Breast Feeding
and *Salmonella* infection [France] 147 (Fe)
are we in midst of a revolution? [Kennell] 303 (Mr)
Breech Presentation see Labor Presentation
Brethine see Terbutaline
Bricanyl see Terbutaline
Bright Disease see Glomerulonephritis
Bronchi
anomalous apical bronchus of right upper lobe, radiological case of month [Young, Fujioka] 615 (Je)
fluid administration and bronchopulmonary dysplasia, lack of association [Spahr] 958 (Oc)
Bronchiolitis
theophylline toxicity in term infants [Simons] 39 (Ja)
Bronkosol see Isoetharine
Bullous Skin Diseases see Skin Diseases, Bullous
Buphthalmos
neurofibromatosis with congenital glaucoma and, in newborn [Satran] 182 (Fe)
Buttocks
injuries and child abuse (letter) [Pascoe] 711 (Jy)

C

C-Peptide see Peptides
Caffeine
acute overdose in neonate [Banner] 495 (My)
Calcification, Pathologic see Calcinosis
Calcinosis
cervical disk calcification in childhood, radiological case of month [Young, Faucher] 701 (Jy)
computerized tomography to define CNS involvement in congenital cytomegalovirus infection (clin. memo.) [Anders] 795 (Au)
Calcitriol
serum 1,25-dihydroxyvitamin D levels in normal children and in vitamin D disorders [Chesney] 135 (Fe)
supranormal 25-hydroxyvitamin D and subnormal 1,25-dihydroxyvitamin D, role in X-linked hypophosphatemic rickets [Chesney] 140 (Fe)
Cambodia
"teach a man to fish" (Chinese proverb) [Sumpter] 1025 (No)
Campomelia
campomelic dysplasia, further elucidation of distinct entity [Hall] 285 (Mr)
Cancer see Neoplasms
Carbohydrate Metabolism, Inborn Errors
uridine diphosphate galactose 4-epimerase deficiency (clin. memo.) [Ichiba] 995 (Oc)
Carpal Tunnel Syndrome
bilateral, in adolescent [Feingold] 394 (Ap)
Carroll, Lewis (Rev C. L. Dodgson) (1832-1898)
Miss Alice Pleasance Liddell, photograph by, 823 (Se)
Catheterization, Heart see Heart Catheterization
Cefaclor
in treatment of otitis media and pharyngitis in children [McLinn] 560 (Je)
Cells
infant nasal mucosal, adherence of *Staphylococcus aureus* to (clin. memo.) [Aly] 522 (My)
Central Nervous System
CNS manifestations of hemolytic-uremic syndrome, relationship to metabolic alterations and prognosis [Bale] 869 (Se)
computerized tomography to define CNS involvement in congenital cytomegalovirus infection (clin. memo.) [Anders] 795 (Au)
Central Nervous System—Continued
infantile degeneration, syndrome of [Holmes] 262 (Mr)
Cerebellar Ataxia
opsoclonus, occult neural crest tumor and, abdominal computerized tomography in diagnosis [Kinast] 1057 (No)
Cerebellar Dyssynergia see Cerebellar Ataxia
Cerebral Embolism and Thrombosis
massive intracranial air embolism, complication of mechanical ventilation (clin. memo.) [Banagale] 799 (Au)
Cerebral Hemorrhage
evaluation of neonatal periventricular-intraventricular hemorrhage, major advance [Volpe] 1023 (No)
in premature, predictive features and outcome [Kosmetatos] 855 (Se)
periventricular, in premature infant, porencephaly from [Pasternak] 673 (Jy)
sector scan ultrasound imaging through anterior fontanelle, use in diagnosing neonatal periventricular-intraventricular hemorrhage [Allan] 1028 (No)
Cerebrospinal Fluid
diphtheroid sepsis in child with no predisposing condition (clin. memo.) [MacDonald] 708 (Jy)
eosinophilia during acute coxsackie B4 viral meningitis (clin. memo.) [Chesney] 703 (Jy)
evaluation of neonatal periventricular-intraventricular hemorrhage, major advance [Volpe] 1023 (No)
isotopic cisternography in tuberculous meningitis of childhood [Özdirim] 572 (Je)
local immunity in mumps meningitis [Morishima] 1060 (No)
neurotransmitter studies, infant with ascorbic acid-responsive tyrosinemia [Stoerner] 492 (My)
Cervical Vertebrae
cervical disk calcification in childhood, radiological case of month [Young, Faucher] 701 (Jy)
Chemotaxis
breast-feeding and *Salmonella* infection [France] 147 (Fe)
mitogenic response to *Toxocara* antigen and chemotactic defect in visceral larva migrans [Caldwell] 845 (Se)
Chest see Thorax
Chickenpox Virus see Varicella-Zoster Virus
Child
small-intestine length in infants and [Siebert] 593 (Je); elongated in prune-belly syndrome (letter) [Miller] (reply) [Siebert] 1182 (De)
Child Abuse
injuries and (letter) [Pascoe] 711 (Jy)
sexual abuse of boys [Ellerstein] 255 (Mr), (letter) [Duncan] 1001 (Oc)
trauma and, importance of medical record [Solomons] 503 (My)
women who abuse their children, implications for pediatric practice [Rosen] 947 (Oc)
Child Behavior
behavioral symptom substitution in children cured of encopresis [Levine] 663 (Jy)
Child Behavior Disorders
hyperactivity, symptom complex or complex symptom? [Levine] 409 (Ap)
nonstandard therapies in developmental disabilities [Golden] 487 (My)
Child Development
nonstandard therapies in developmental disabilities [Golden] 487 (My)
ring chromosome 15 and failure to thrive (clin. memo.) [Kousseff] 798 (Au)
Child, Hospitalized
malnourished, cell-mediated immune defects and infection, study of [Carney] 824 (Se)
Child Neglect see Child Abuse
Child Nutrition
diets for children and adolescents that meet
Child Nutrition—Continued
dietary goals [Dwyer] 1073 (No)
Child, Preschool
urinary infection in infants and, 5-year follow-up [Siegel] 369 (Ap)
Chlamydia Infections
severe neonatal chlamydial pneumonitis (clin. memo.) [Sagy] 89 (Ja)
Cholangiography
acquired bile duct stricture in childhood related to blunt trauma, case report, literature review [Kendall] 851 (Se)
Cholelithiasis
associated with hemolytic-uremic syndrome (clin. memo.) [Schweighofer] 622 (Je)
sonographic diagnosis in childhood [Buschi] 575 (Je)
Cholestasis
acquired bile duct stricture in childhood related to blunt trauma, case report, literature review [Kendall] 851 (Se)
infantile cholestatic liver disease (letters) [Harris] 623 (Je), 801 (Au), (reply) [Rosenthal] 802 (Au)
Cholesterol
essential fatty acids revisited [Friedman] 397 (Ap)
Chondrodysplasia, Hereditary Deforming see Exostoses, Multiple
Chromium
trace elements in fetus and young infant [Shaw] 74 (Ja)
Chromosome Aberrations
live-born triploid (clin. memo.) [Fraikor] 988 (Oc)
partial trisomy 9q due to maternal 9/17 translocation [Aftimos] 848 (Se)
Chromosome Abnormalities see also Karyotyping
ring chromosome 15 and failure to thrive (clin. memo.) [Kousseff] 798 (Au)
Chromosomes see Karyotyping
Chromosomes, Human
ring chromosome 15 and failure to thrive (clin. memo.) [Kousseff] 798 (Au)
Cimetidine
in pregnancy, apparent transient liver impairment in newborn (clin. memo.) [Glade] 87 (Ja)
Circumcision
and patient education [Gorske] 527 (My)
and risk of cancer of penis, life-table analysis [Kochen] 484 (My)
effect on transcutaneous Po_2 in term infants [Rawlings] 676 (Jy)
neonatal, necrotizing fasciitis after [Woodside] 301 (Mr), (letter) [Katz] (reply) [Woodside] 1098 (No)
Cisternography, Myelographic see Myelography
Cleft Lip
ankyloblepharon filiforme adnatum, congenital eyelid-band syndromes [Rosenman] 751 (Au)
lip pits, cleft lip and/or palate, and congenital heart disease [Pauli] 293 (Mr)
Cleft Palate
ankyloblepharon filiforme adnatum, congenital eyelid-band syndromes [Rosenman] 751 (Au)
lip pits, cleft lip and/or palate, and congenital heart disease [Pauli] 293 (Mr)
Cleidocranial Dysostosis
severe micrognathism, bilateral absence of thumbs and first metatarsal bone, distal aphalangia, and new genetic syndrome [Yunis] 649 (Jy)
Clonazepam
nonketotic hyperglycinemia, effects of therapy with strychnine [Warburton] 273 (Mr)
Clostridium
chronic otitis media in children, microbiological studies [Brook] 564 (Je)
infection in mother and infant (clin. memo).

Clostridium—Continued
[Chaney] 1175 (De)
Coburn, A. L.
Miss Alice Pleasance Liddell, modern print of Lewis Carroll negative by, 823 (Se)
Coitus
condoms for sexually active adolescents [Bergman] 247 (Mr); advertising condoms (letters) [Friday, Feroli] (reply) [Bergman] 1000 (Oc)
Cold
heparin-precipitable cryoprecipitate in child with cold urticaria (clin. memo.) [Hurwitz] 797 (Au)
infectious mononucleosis initially seen as acrocyanosis induced by, association with auto-anti-M and anti-I antibodies [Dickerman] 159 (Fe)
Colitis, Pseudomembranous see Enterocolitis, Acute
Collaborative Study of Children Treated for Phenylketonuria
diagnosis of phenylketonuria [O'Flynn] 769 (Au)
Coloring Agents, Food see Food Coloring Agents
Colostrum
breast-feeding and *Salmonella* infection [France] 147 (Fe)
Coma
CNS manifestations of hemolytic-uremic syndrome, relationship to metabolic alterations and prognosis [Bale] 869 (Se)
Communicable Diseases
bacterial immunizations, review [Harrison] 184 (Fe)
Comprehensive Health Care
pediatrics and record-keeping (letter) [Sparling] (reply) [Margolis] 326 (Mr)
Computerized Tomography, X-Ray see Tomography, X-Ray Computed
Conn's Disease see Hyperaldosteronism
Consumption Coagulopathy see Disseminated Intravascular Coagulation
Contraceptive Devices, Male
condoms for sexually active adolescents [Bergman] 247 (Mr); advertising condoms (letters) [Friday, Feroli] (reply) [Bergman] 1000 (Oc)
Contracture
Marden-Walker syndrome (letter) [Fitch] 93 (Ja)
Convulsions
acute caffeine overdose in neonate [Banner] 495 (My)
acute isoniazid poisoning in childhood [Miller] 290 (Mr)
CNS manifestations of hemolytic-uremic syndrome, relationship to metabolic alterations and prognosis [Bale] 869 (Se)
encephalopathy in young children with moderate chronic renal failure [Bale] 581 (Je)
lidocaine ingestion (clin. memo.) [Sakai] 323 (Mr)
metabolic studies in child with pancreatic insulinoma [Ginsberg-Fellner] 64 (Ja)
progressive facial hemiatrophy associated with Ewing's sarcoma [Paradise] 1065 (No)
Copper
copper ligands in human milk, vehicle for copper supplementation in Menkes' disease? (letter) [Lönnerdal] 802 (Au)
infantile nutritional copper deficiency, radiological case of month [Young, Bennani-Smires] 1155 (De)
trace elements in fetus and young infant [Shaw] 74 (Ja)
Cor Pulmonale see Pulmonary Heart Disease
Coronary Vessels
myocardial infarction in neonate with normal heart and coronary arteries [Kilbride] 759 (Au)
Corpus Luteum
hemorrhagicum, unusual complication of anticoagulant therapy (clin. memo.) [Shapiro] 523 (My)
Corticoids see Adrenal Cortex Hormones
Corticosteroids see Adrenal Cortex Hormones
Corticotropin
plasma, in congential adrenal hyperplasia, importance in long-term management [LaFranchi] 1068 (No)
Corynebacterium Infections
diphtheroid sepsis in child with no predisposing condition (clin. memo.) [MacDonald] 708 (Jy)
Coxsackie B Viruses
brachial plexus neuropathy [Charles] 299 (Mr)
CSF eosinophilia during acute coxsackie B4 viral meningitis (clin. memo.) [Chesney] 703 (Jy)
Cranial Fossa, Posterior see Skull
Craniofacial Dysostosis
Crouzon's disease data (letter) [Ruben] 801 (Au)
Craniosynostoses
radial aplasia with, Baller-Gerold syndrome (clin. memo.) **133**:1279 (De), correction, **134**:363 (Ap)
Cranium see Skull
Creatinine
renal venous thrombosis in neonates [Rasoulpour] 276 (Mr)
Criminal Law see Jurisprudence
Cross Infection
necrotizing enterocolitis, epidemic following outbreak of *Enterobacter cloacae* type 3305573 in neonatal intensive care unit [Powell] 1152 (De)
nosocomial pertussis, failure of erythromycin treatment and prophylaxis (clin. memo.) [Halsey] 521 (My), (letter) [Bass] 1178 (De)
nosocomial pertussis, possible spread by hospital visitor (clin. memo.) [Valenti] 520 (My)
nosocomial scalded skin syndrome, Ritter's disease caused by phage group 3 *Staphylococcus aureus* [Florman] 1043 (No)
nosocomial transmission of bacteriophage type 7/11/12 group B streptococci in special care nursery [Boyer] 964 (Oc)
Crouzon's Disease see Craniofacial Dysostosis
Cultural Deprivation
"teach a man to fish" (Chinese proverb) [Sumpter] 1025 (No)
Cyanosis
hyperuricemia in cyanotic congenital heart disease (letter) [Young] 902 (Se)
infectious mononucleosis initially seen as cold-induced acrocyanosis, association with auto-anti-M and anti-I antibodies [Dickerman] 159 (Fe)
Cyclophosphamide
nasal polymorphic reticulosis in child [Houghton] 387 (Ap)
Cystic Fibrosis
acute pulmonary exacerbations in, double-blind trial of tobramycin and placebo [Wientzen] 1134 (De)
elevated meconium lactase activity, use as screening test for [Berry] 930 (Oc)
essential fatty acids revisited [Friedman] 397 (Ap)
heart failure in, treatment and prognosis of cor pulmonale with failure of right side of heart [Stern] 267 (Mr), (letter) [Marino] (reply) [Stern] 1179 (De)
hemoglobin desaturation, occurrence during sleep in [Francis] 734 (Au)
incidence of meconium abnormalities in newborn infants with [Rosenstein] 72 (Ja)
intravenous aminophylline in, pharmacokinetics and effect on pulmonary function [Larsen] 1143 (De)
isolated growth hormone deficiency and (clin. memo.) [Hubbard] 317 (Mr)
Cystic Fibrosis—Continued
menarchal determinants in [Moshang] 1139 (De)
screening of newborns for [Gibson] 925 (Oc)
seropositive rheumatoid arthritis in patient with (clin. memo.) [Sagransky] 319 (Mr)
sleep hypoxemia in patients with [Mansell] 733 (Au)
sleep hypoxemia in young adults with [Stokes] 741 (Au)
Cystine
argininosuccinicaciduria, hair abnormality revisited (clin. memo.) [Potter] 1095 (No)
Cysts
arachnoid, computerized tomography in evaluation of isosexual precocity [Hung] 25 (Ja), (letter) [Schwartz] 802 (Au)
enteric duplication, picture of month [Gellis, Pierce] 985 (Oc)
porencephaly from periventricular intracerebral hemorrhage in premature infant [Pasternak] 673 (Jy)
pyogenic gingival, in infancy, group A β-hemolytic streptococci causing (clin. memo.) [Patamasucon] 617 (Je)
Cytogenetics see Chromosome Abnormalities; Karyotyping
Cytomegaloviruses
computerized tomography to define CNS involvement in congenital infection (clin. memo.) [Anders] 795 (Au)

D

Dapsone
50-mg, danger of doses to children (letter) [Kahn] (reply) [Jarratt] 623 (Je)
Darvon see Propoxyphene
Deafness
hearing loss and learning disability (letter) [Hersher] (reply) [Zinkus] 94 (Ja)
Death, Sudden
laryngeal mucous gland excess in victims of sudden infant death [Fink] 144 (Fe)
role of respiratory infection in intrathoracic petechiae, implications for sudden infant death [Guntheroth] 364 (Ap)
Defecation see Encopresis
Deferoxamine
acute iron poisoning, review [Robotham] 875 (Se)
Deglutition Disorders
fibromuscular hamartoma of esophagus in infant [Beckerman] 153 (Fe)
Dehydration
hypernatremic, of infancy, epidemiologic review [Paneth] 785 (Au), correction, 1096 (No)
Dehydroascorbic Acid see Ascorbic Acid
Delivery see also Labor Presentation
alternative birthing center, one family's experience [Butzen] 348 (Ap)
are we in midst of a revolution? [Kennell] 303 (Mr)
pregnancy, neonatal complications and, among autistic children [Deykin] 860 (Se)
Depression, Bipolar see Psychoses, Manic-Depressive
Dermatitis Exfoliativa
nosocomial scalded skin syndrome, Ritter's disease caused by phage group 3 *Staphylococcus aureus* [Florman] 1043 (No)
Dermoid Cyst
intracranial, diagnosis by computerized tomography (clin. memo.) [Maulsby] 420 (Ap)
Desitin
epidemiology of poisoning from drug products [Saracino] 763 (Au)
De Toni-Debre-Fanconi Syndrome see Fanconi Syndrome
Devices see Equipment and Supplies

Diabetes Mellitus
psychological factors in (letter) [Laron] (reply) [Greydanus] 1004 (Oc)
Diabetes Mellitus, Juvenile
Hashimoto's thyroiditis, juvenile rheumatoid arthritis and (letter) [Fisher] 93 (Ja)
urine C-peptide, β-cell function, and insulin requirement [Rappaport] 1129 (De)
Diagnosis
recurrent abdominal pain in childhood [Lebenthal] 347 (Ap), (letter) [Rapp] 998 (Oc)
Diaminodiphenylsulfone see Dapsone
Diaphragm
liver herniation presenting as respiratory distress and cardiomegaly (clin. memo.) [Hofschire] 1091 (No)
Diaphyseal Aclasis see Exostoses, Multiple
Diaphyseal Dysplasia, Progressive see Bone Diseases, Developmental
Diarrhea, Infantile
chronic "diarrhea" and diet (letter) [Graham] (reply) [Cohen] 526 (My)
hypernatremic dehydration of infancy, epidemiologic review [Paneth] 785 (Au), correction, 1096 (No)
vasoactive intestinal peptide secreting tumors of childhood [Kaplan] 21 (Ja)
Diasone see Dapsone
Diazepam
epidemiology of poisoning from drug products [Saracino] 763 (Au)
Diet
chronic "diarrhea" and (letter) [Graham] (reply) [Cohen] 526 (My)
for children and adolescents that meet dietary goals [Dwyer] 1073 (No)
infantile nutritional copper deficiency, radiological case of month [Young, Bennani-Smires] 1155 (De)
Dietary Fats
chronic "diarrhea" and diet (letter) [Graham] (reply) [Cohen] 526 (My)
Dietary Proteins
vegetarianism in children [MacLean] 513 (My)
Diformyl Dapsone see Dapsone
Digitalis
thiamine-deficiency-related cardiac failure (letter) [Anteski] 1098, (reply) [Moran] 1099 (No)
Dimetapp
epidemiology of poisoning from drug products [Saracino] 763 (Au)
Diphtheria Toxin
diphtheria-tetanus skin testing, clinical value for delayed hypersensitivity [Kaufman] 479 (My)
Diphtheria Toxoid
active immunization in large child-caring institution, *60 Years Ago in AJDC*, 637 (Jy)
Diplococcus Pneumoniae see Streptococcus Pneumoniae
Disk, Intervertebral see Intervertebral Disk
Disseminated Intravascular Coagulation
Reye's syndrome associated with acute renal failure and (letter) [Muntean] 999 (Oc)
Diuretics
thiamine-deficiency-related cardiac failure (letter) [Anteski] 1098, (reply) [Moran] 1099 (No)
Diverticulosis, Esophageal see Esophageal Diverticula
Dose-Response Relationship, Drug
naloxone, underdosage after narcotic poisoning [Moore] 156 (Fe)
Down's Syndrome
congenital leukemoid reaction followed by fatal leukemia, case with [Lin] 939 (Oc)
5-hydroxytryptophan and pyridoxine, effects in young children with [Pueschel] 838 (Se)
triplo-X and Down's syndrome (letter) [Yeatman] (reply) [Gardner] 527 (My)
Doxepin
poisoning in child (clin. memo.) [Walter] 202 (Fe)
Drainage, Suction see Suction
Dropsy see Edema
Drug Addiction see Drug Dependence
Drug Dependence
early growth patterns of methadone-addicted infants [Chasnoff] 1049 (No)
Drug Habituation see Drug Dependence
Drug Hypersensitivity
epidemiology of poisoning from drug products [Saracino] 763 (Au)
Drug Resistance, Microbial
antibiotic-resistant streptococci (letter) [Gentry] 801 (Au)
Drug Withdrawal Symptoms
early growth patterns of methadone-addicted infants [Chasnoff] 1049 (No)
Drugs
advertising in *AJDC* (letter) [Barna] (reply) [Barclay] 902 (Se)
Duane's Syndrome see Ophthalmoplegia
Ductus Arteriosus
effect of circumcision on transcutaneous Po_2 in term infants [Rawlings] 676 (Jy)
prostaglandins [Olley] 688 (Jy)
Ductus Arteriosus, Patent
fluid administration and bronchopulmonary dysplasia, lack of association [Spahr] 958 (Oc)
Duodenum
immunoglobulin concentrations in duodenal fluid of infants and children [Lebenthal] 834 (Se)
Dwarfism
campomelic dysplasia, further elucidation of distinct entity [Hall] 285 (Mr)
long-limbed campomelic, radiologic and pathologic study [Austin] 1035 (No)
severe, Rothmund-Thomson syndrome with [Hall] 165 (Fe)
Dysostosis, Cleidocranial see Cleidocranial Dysostosis
Dysostosis, Craniofacial see Craniofacial Dysostosis
Dysphagia see Deglutition Disorders
Dystonia see Muscle Dystonia

E

Ear, Middle
disparate cultures of fluids in, results from children with bilateral otitis media [Pelton] 951 (Oc)
Ebstein's Anomaly
of tricuspid valve associated with prenatal exposure to lithium carbonate (clin. memo.) [Park] 703 (Jy)
Echocardiography
cardiac function in primary hypothyroidism [Hayford] 556 (Je)
cardiomyopathy of hypothyroidism revisited, are children different than adults? [Santos] 547 (Je)
endocarditis in newborn [McGuinness] 577 (Je)
hemoglobin desaturation, occurrence during sleep in cystic fibrosis [Francis] 734 (Au)
Ectopia Cordis see Heart Defects, Congenital
Edema
dorsal pedal, and excessive perspiration, TAR syndrome (clin. memo.) [Feingold] 895 (Se)
hydrops of gallbladder (clin. memo.) [Neu] 891 (Se)
intrapericardial teratoma, new and treatable cause of hydrops fetalis (clin. memo.) [Branfield] 1174 (De)
water retention in pneumonia, *60 Years Ago in AJDC* 478 (My)
Edema, Cardiac see Heart Failure, Congestive
Education of Patients see Patient Education
Electrolytes see Fluid Therapy
Embolism, Air
massive intracranial, complication of mechanical ventilation (clin. memo.) [Banagale] 799 (Au)
systemic, secondary to respiratory therapy, radiological case of month [Young, Kogutt] 983 (Oc)
Emotions
psychological factors in diabetes mellitus (letter) [Laron] (reply) [Greydanus] 1004 (Oc)
Empyema
pneumococcal, outcome of medical management [Murphy] 659 (Jy)
Encopresis
behavioral symptom substitution in children cured of [Levine] 663 (Jy)
Endocarditis
in newborn [McGuinness] 577 (Je)
Enteral Feeding
necrotizing enterocolitis and [Goldman] 553 (Je)
necrotizing enterocolitis and, is too much just too much? [Eidelman] 545 (Je)
Enteral Hyperalimentation see Enteral Feeding
Enteric Hormones see Gastrointestinal Hormones
Enterobacter see Enterobacteriaceae
Enterobacteriaceae
necrotizing enterocolitis, epidemic following outbreak of *Enterobacter cloacae* type 3305573 in neonatal intensive care unit [Powell] 1152 (De)
Enterocolitis, Acute
feeding and necrotizing enterocolitis [Goldman] 553 (Je)
necrotizing, and enteral feeding, is too much just too much? [Eidelman] 545 (Je)
necrotizing, and feeding patterns (letter) [Goldman] (reply) [Guinan] 207 (Fe)
necrotizing, epidemic following outbreak of *Enterobacter cloacae* type 3305573 in neonatal intensive care unit [Powell] 1152 (De)
necrotizing, milk curd obstruction mimicking (clin. memo.) [Berkowitz] 989 (Oc)
Enterocolitis, Necrotizing see Enterocolitis, Acute
Enterocolitis, Pseudomembranous see Enterocolitis, Acute
Enteropathy, Exudative see Protein-Losing Enteropathies
Enzymes
trace elements in fetus and young infant, copper, manganese, selenium and chromium [Shaw] 74 (Ja)
Eosinophilia
CSF, during acute coxsackie B4 viral meningitis (clin. memo.) [Chesney] 703 (Jy)
Epidemiologic Methods see Mass Screening
Epidemiology
hypernatremic dehydration of infancy, epidemiologic review [Paneth] 785 (Au), correction, 1096 (No)
Epidermal Necrolysis, Toxic
nosocomial scalded skin syndrome, Ritter's disease caused by phage group 3 *Staphylococcus aureus* [Florman] 1043 (No)
Epimerases see Isomerases
Epinephrine
management of acute asthma in childhood, randomized evaluation of β-adrenergic agents [Schwartz] 474 (My)
Epithelium
adherence of *Staphylococcus aureus* to infant nasal mucosal cells (clin. memo.) [Aly] 522 (My)
Eponyms
triplo-X and Down's syndrome (letter) [Yeatman] (reply) [Gardner] 527 (My)
Equipment and Supplies
use of side-hole endotracheal tube adapter for tracheal aspiration [Zmora] 250 (Mr)
Ergocalciferol
supranormal 25-hydroxyvitamin D and subnormal 1,25-dihydroxyvitamin D, role in X-linked hypophosphatemic rickets [Chesney] 140 (Fe)
Erythredema Polyneuropathy see Acrodynia

Erythrocytes
uridine diphosphate galactose 4-epimerase deficiency (clin. memo.) [Ichiba] 995 (Oc)
values in low-birth-weight infants during first 7 weeks of life [Stockman] 945 (Oc)
Erythrocytes, Abnormal
macrocytosis and pure RBC anemia caused by azathioprine [DeClerck] 377 (Ap)
Erythroderma Ichthyosiforme, Bullous see Skin Diseases, Bullous
Erythromycin
nosocomial pertussis, failure of treatment and prophylaxis with (clin. memo.) [Halsey] 521 (My), (letter) [Bass] 1178 (De)
streptococci resistant to (letter) [Gentry] 801 (Au)
Eskimos
acute glomerulonephritis and streptococcal skin lesions in Eskimo children [Margolis] 681 (Jy)
Esophageal Diverticula
pseudodiverticulum of esophagus in newborn infant (clin. memo.) [Urrutia] 417 (Ap)
Esophageal Neoplasms
fibromuscular hamartoma, in infant [Beckerman] 153 (Fe)
Esophageal Perforation
in premature infants, comments on diagnosis [Clarke] 367 (Ap)
pseudodiverticulum of esophagus in newborn infant (clin. memo.) [Urrutia] 417 (Ap)
Esophageal Reflux
string test for gastroesophageal reflux [Liebman] 755 (Au)
surgical treatment in children, results of Nissen's fundoplication in 100 children [Leape] 935 (Oc)
ESSAY
hyperactivity, symptom complex or complex symptom? [Levine] 409 (Ap)
Essential Polyarteritis see Periarteritis Nodosa
Ethanol see Alcohol, Ethyl
Ewing's Tumor see Sarcoma, Ewing's
Exophthalmic Goiter see Goiter, Exophthalmic
Exostoses, Multiple
metaphyseal chondrodysplasia, Schmid type, picture of month [Gellis, Pavone] 699 (Jy)
Expiratory Forced Flow Rates see Forced Expiratory Flow Rates
Extremities
campomelic dysplasia, further elucidation of distinct entity [Hall] 285 (Mr)
infectious mononucleosis initially seen as cold-induced acrocyanosis, association with auto-anti-M and anti-I antibodies [Dickerman] 159 (Fe)
juvenile aponeurotic fibroma, radiological case of month [Young, Lowell] 195 (Fe)
long-limbed campomelic dwarfism, radiologic and pathologic study [Austin] 1035 (No)
metaphyseal chondrodysplasia, Schmid type, picture of month [Gellis, Pavone] 699 (Jy)
Eye Manifestations
eye involvement in anaphylactoid purpura (clin. memo.) [Lorentz] 524 (My)
Eye Neoplasms
Ota's nevus, picture of month [Gellis, Fikar] 1083 (No)
Eyelids
ankyloblepharon filiforme adnatum, congenital eyelid-band syndromes [Rosenman] 751 (Au)
Marden-Walker syndrome (letter) [Fitch] 93 (Ja)
neurofibromatosis with congenital glaucoma and buphthalmos in newborn [Satran] 182 (Fe)

F

Facial Hemiatrophy
hemifacial atrophy (Romberg's syndrome), picture of month [Gellis, Tirosh] 883 (Se)
progressive, associated with Ewing's sarcoma [Paradise] 1065 (No)
Faculty, Medical
critical academic mass [Bergstrom] 129 (Fe)
Family
tracheoesophageal fistula in parent and offspring, rare occurrence (clin. memo.) [Kiesewetter] 896 (Se)
Fanconi Syndrome
serum 1,25-dihydroxyvitamin D levels in normal children and in vitamin D disorders [Chesney] 135 (Fe)
Fascia
juvenile aponeurotic fibroma, radiological case of month [Young, Lowell] 195 (Fe)
necrotizing fasciitis after neonatal circumcision [Woodside] 301 (Mr), (letter) [Katz] (reply) [Woodside] 1098 (No)
Fatty Acids, Essential
revisited [Friedman] 397 (Ap)
Fatty Acids, Unsaturated
essential fatty acids revisited [Friedman] 397 (Ap)
vitamin E and neonate [Ehrenkranz] 1157 (De)
Fecal Incontinence see Encopresis
Feces see Melena
Feer's Disease see Acrodynia
Fellozine see Promethazine
Fetal Anoxia see Asphyxia Neonatorum
Fetal Presentation see Labor Presentation
Fetoscopy see Prenatal Diagnosis
Fetuins see Alpha Fetoproteins
Fetus see also Maternal-Fetal Exchange
molybdenum metabolism (letter) [Beemer] 1097 (reply) [Shaw] 1098 (No)
trace elements in, copper, manganese, selenium, and chromium [Shaw] 74 (Ja)
Fever
acute febrile mucocutaneous lymph node syndrome [Yanagihara] 603 (Je)
elimination of acetone bodies during infectious fevers, *60 Years Ago in AJDC*, 158 (Fe)
phobia, misconceptions of parents about [Schmitt] 176 (Fe), (letter) [Cohen] 1001 (Oc)
pneumococcal empyema, outcome of medical management [Murphy] 659 (Jy)
prostaglandins [Olley] 688 (Jy)
Staphylococcus aureus sepsis in childhood malignancy [Miser] 831 (Se)
subacute thyroiditis in 4½-year-old girl (clin. memo.) [Buchta] 1090 (No)
Fibrocystic Disease of Pancreas see Cystic Fibrosis
Fibroma
juvenile aponeurotic, radiological case of month [Young, Lowell] 195 (Fe)
Fingers
cleidocranial dysostosis, severe micrognathism, bilateral absence of thumbs and first metatarsal bone, and distal aphalangia, new genetic syndrome [Yunis] 649 (Jy)
Fistula see Tracheoesophageal Fistula
Fluid Therapy
fluid administration and bronchopulmonary dysplasia, lack of association [Spahr] 958 (Oc)
Fluorides
supplements for children, survey of physicians' prescription practices [Margolis] 865 (Se)
Flurazepam
epidemiology of poisoning from drug products [Saracino] 763 (Au)
Follow-Up Studies
4-year, RA27/3 rubella vaccine, [Balfour] 350 (Ap)
5-year, urinary infection in infants and preschool children [Siegel] 369 (Ap)
Food
foreign body in airway, review of 200 cases [Blazer] 68 (Ja)
Food Additives
and hyperkinesis, new evidence on, critical analysis [Wender] 1122; in rebuttal [Swanson] 1124, [Weiss] 1126 (De)
Food Additives—Continued
nonstandard therapies in developmental disabilities [Golden] 487 (My)
Food Coloring Agents
new evidence on food additives and hyperkinesis, critical analysis [Wender] 1122; in rebuttal [Swanson] 1124, [Weiss] 1126 (De)
Food Hypersensitivity
critical review and practical approach [Bock] 973 (Oc)
recurrent abdominal pain (letter) [Crook] 326, (reply) [Stickler] 327 (Mr)
Food, Infant see Infant Food
Foot
TAR syndrome, dorsal pedal edema and excessive perspiration (clin. memo.) [Feingold] 895 (Se)
Forced Expiratory Flow Rates
intravenous aminophylline therapy for asthma, comparison of 2 methods of administration [Goldberg] 596 (Je)
Foreign Bodies
in airway, review of 200 cases [Blazer] 68 (Ja)
migration of inflorescence, complications of grass head aspiration (clin. memo.) [Steele] 704 (Jy)
Foreign Body Migration see Foreign Bodies
Forensic Medicine see Jurisprudence
Fractures
traumatic ischial apophyseolysis, radiological case of month [Young, Tan] 885 (Se)
Friedreich's Ataxia
with acute cardiomyopathy [Berg] 390 (Ap)
Fungizone see Amphotericin B
Fusobacterium necrophorum
sepsis, metastatic complications of, 2 cases of Lemierre's postanginal septicemia [Vogel] 356 (Ap)

G

Gallbladder
hydrops of (clin. memo.) [Neu] 891 (Se)
Gallstones see Cholelithiasis
Ganglioneuroma
functioning tumors [Voorhess] 14 (Ja)
vasoactive intestinal peptide secreting tumors of childhood [Kaplan] 21 (Ja)
Ganphen see Promethazine
Gases
pancuronium and abnormal abdominal roentgenograms [Dillard] 821 (Se)
Gasser's Syndrome see Hemolytic-Uremic Syndrome
Gastroenteritis
rotavirus, in Washington, DC, area, incidence of cases resulting in admission to hospital [Rodriguez] 777 (Au)
Gastrointestinal Hormones
functioning tumors [Voorhess] 14 (Ja)
vasoactive intestinal peptide secreting tumors of childhood [Kaplan] 21 (Ja)
Gastroschisis
anomaly of umbilical ring as factor in (letter) [Gaillard] 1179 (De)
Gastrostomy see Enteral Feeding
Genetic Counseling
ankyloblepharon filiforme adnatum, congenital eyelid-band syndromes [Rosenman] 751 (Au)
familial pulmonary atresia, occurrence with ventricular septal defect [DiChiara] 506 (My)
Genetics, Human see Genetics, Medical
Genetics, Medical see also Chromosome Abnormalities
asymptomatic familial elevation of serum alkaline phosphatase levels (clin. memo.) [Parker] 1094 (No)
campomelic dysplasia, further elucidation of distinct entity [Hall] 285 (Mr)
cleidocranial dysostosis, severe micrognathism, bilateral absence of thumbs and first metatar-

Genetics, Medical—Continued
sal bone, and distal aphalangia, new genetic syndrome [Yunis] 649 (Jy)
familial pulmonary atresia, occurrence with ventricular septal defect [DiChiara] 506 (My)
gastroschisis (letter) [Gaillard] 1179 (De)
implications of ultrasonographic detection of in utero cystic hygroma (letter) [Rutledge] 999, (reply) [Haimovici] 1000 (Oc)
increased amniotic fluid α-fetoprotein, familial hydrocephalus, and renal dysmorphology (clin. memo.) [Sinclair-Smith] 619 (Je)
long-limbed campomelic dwarfism, radiologic and pathologic study [Austin] 1035 (No)
neonatal von Willebrand's disease, diagnostic difficulty at birth (clin. memo.) [Weinger] 793 (Au)
osteopoikilosis, familial documentation, radiological case of month [Young, Gershman] 415 (Ap)
regression and clinical research [Brown] 549 (Je), correction, 746 (Au)
syndrome of infantile CNS degeneration [Holmes] 262 (Mr)
tracheoesophageal fistula in parent and offspring, rare occurrence (clin. memo.) [Kiesewetter] 896 (Se)
Genitalia
injuries and child abuse (letter) [Pascoe] 711 (Jy)
Giant Cells
giant cell pneumonia, radiological case of month [Young, Ross] 511 (My)
Giardiasis
apparent protein-losing enteropathy associated with (clin. memo.) [Sherman] 893 (Se)
Gingiva
group A β-hemolytic streptococci causing pyogenic gingival cyst in infancy (clin. memo.) [Patamasucon] 617 (Je)
Glandular Fever see Infectious Mononucleosis
Glaucoma
congenital, neurofibromatosis with buphthalmos and, in newborn [Satran] 182 (Fe)
Glomerulonephritis see also Kidney Failure, Chronic
acute, and streptococcal skin lesions in Eskimo children [Margolis] 681 (Jy)
Glomerulosclerosis, Focal see Glomerulonephritis
Glossitis
acute, and septicemia owing to *Haemophilus influenzae* type B (clin. memo.) [San Joaquin] 91 (Ja)
Glucose
dextrose tolerance in atrophic infants, *60 Years Ago in AJDC*, 45 (Ja)
Glutamic-Oxaloacetic Transaminase see Aspartate Aminotransferase
Gluteal Region see Buttocks
Glycine
nonketotic hyperglycinemia, effects of therapy with strychnine [Warburton] 273 (Mr)
Goiter
hyperfunctioning thyroid nodules in children [Abe] 961 (Oc)
Goiter, Exophthalmic
unilateral thyroid enlargement with hyperthyroidism (clin. memo.) [Leung] 890 (Se)
Gonadal Dysgenesis
long-limbed campomelic dwarfism, radiologic and pathologic study [Austin] 1035 (No)
Gonadal Dysgenesis, 45,X, 45,XO see Turner's Syndrome
Gonorrhea
spectinomycin therapy for, in prepubertal children [Rettig] 359 (Ap)
Gonosomes see Sex Chromosomes
Granulocytopenia see Agranulocytosis
Granuloma Gangraenescens see Granuloma, Lethal Midline
Granuloma, Lethal Midline
nasal polymorphic reticulosis in child [Houghton] 387 (Ap)
Granulomatous Disease, Chronic
aspergillosis in, therapeutic considerations (clin. memo.) [Corrado] 1092 (No)
pneumatosis intestinalis, occurrence of immunologically compromised child [Kleinman] 1149 (De)
Grasses
migration of inflorescence, complications of grass head aspiration (clin. memo.) [Steele] 704 (Jy)
Graves' Disease see Goiter, Exophthalmic
Great Britain
fate of Special Care Baby Unit in London Hospital (letter from abroad) [Barrie] 431 (Ap)
Growth
early patterns of methadone-addicted infants [Chasnoff] 1049 (No)
vegetarianism in children [MacLean] 513 (My)
Growth Disorders see also Bone Diseases, Developmental
syndrome of infantile CNS degeneration [Holmes] 262 (Mr)
Growth Hormone, Pituitary see Somatotropin
Guerin-Stern Syndrome see Arthrogryposis
Gums see Gingiva

H

Haemophilus influenzae
bacteremias due to *Streptococcus pneumoniae* and, occurrence and course in children with cancer [Siber] 668 (Jy)
disparate cultures of middle ear fluids, results from children with bilateral otitis media [Pelton] 951 (Oc)
type B, acute glossitis septicemia owing to (clin. memo.) [San Joaquin] 91 (Ja)
Haemophilus pneumoniae
chronic otitis media in children, microbiological studies [Brook] 564 (Je)
Hair
argininosuccinicaciduria, hair abnormality revisited (clin. memo.) [Potter] 1095 (No)
changes in zinc metabolism during course of nephrotic syndrome [Reimold] 46 (Ja)
copper ligands in human milk, vehicle for copper supplementation in Menkes' disease? (letter) [Lönnerdal] 802 (Au)
Hamartoma
fibromuscular, of esophagus in infant [Beckerman] 153 (Fe)
Harelip see Cleft Lip
Hashimoto's Disease see Thyroiditis, Lymphomatous
Head
'breech,' with brow presentation (clin. memo.) [Wassman] 994 (Oc)
Head and Neck Neoplasms
hygroma (cystic lymphangioma), diagnosis by ultrasound, radiological case of month [Young, Haimovici] 311 (Mr); genetic implications (letter) [Rutledge] 999, (reply) [Haimovici] 1000 (Oc)
Health Education
fever phobia, misconceptions of parents about fevers [Schmitt] 176 (Fe), (letter) [Cohen] 1001 (Oc)
Hearing
Crouzon's disease data (letter) [Ruben] 801 (Au)
Hearing Loss, Partial
and learning disability (letter) [Hersher] (reply) [Zinkus] 94 (Ja)
Heart
cardiac function in primary hypothyroidism [Hayford] 556 (Je)
cardiomyopathy of hypothyroidism revisited, are children different than adults? [Santos] 547 (Je)
normal coronary arteries and, myocardial infarction in neonate with [Kilbride] 759 (Au)
Heart Abnormalities see Heart Defects, Congenital
Heart Catheterization
pulmonary veno-occlusive disease appearing as acute, recurrent abdominal pain (clin. memo.) [Weinberg] 86 (Ja)
Heart Defects, Congenital
cyanotic, hyperuricemia in (letter) [Young] 902 (Se)
familial pulmonary atresia, occurrence with ventricular septal defect [DiChiara] 506 (My)
lip pits, cleft lip and/or palate, and congenital heart disease [Pauli] 293 (Mr)
Heart Diseases
Friedreich's ataxia with acute cardiomyopathy [Berg] 390 (Ap)
Heart Enlargement
liver herniation presenting as respiratory distress and cardiomegaly (clin. memo.) [Hofschire] 1091 (No)
Heart Failure, Congestive
Friedreich's ataxia with acute cardiomyopathy [Berg] 390 (Ap)
in cystic fibrosis, treatment and prognosis of cor pulmonale with failure of right side of heart [Stern] 267 (Mr), (letter) [Marino] (reply) [Stern] 1179 (De)
thiamine-deficiency-related (letter) [Anteski] 1098, (reply) [Moran] 1099 (No)
Heart Neoplasms
intrapericardial teratoma, new and treatable cause of hydrops fetalis (clin. memo.) [Banfield] 1174 (De)
Heart Septal Defects, Ventricular
familial pulmonary atresia, occurrence with [DiChiara] 506 (My)
Heart Surgery
open, inappropriate secretion of antidiuretic hormone after [Ting] 873 (Se)
Hemagglutination Inhibition Tests
measles-specific lymphocyte reactivity and serum antibody in subjects with different measles histories [Krause] 567 (Je)
Hematemesis
and melena in infant (clin. memo.) [Roth] 994 (Oc)
Hematuria
renal venous thrombosis in neonates [Rasoulpour] 276 (Mr)
Hemoglobins
desaturation, occurrence during sleep in cystic fibrosis [Francis] 734 (Au)
RBC values in low-birth-weight infants during first 7 weeks of life [Stockman] 945 (Oc)
Hemoglobins, Abnormal
screening newborns for sickle cell anemia (letters) [Smith, Grover] 1180, [Detter, Rao] 1181, (replies) [Rubin] 1181, [Miller] 1182 (De)
Hemolysis see Anemia, Hemolytic
Hemolytic-Uremic Syndrome
cholelithiasis associated with (clin. memo.) [Schweighofer] 622 (Je)
CNS manifestations of, relationship to metabolic alterations and prognosis [Bale] 869 (Se)
simultaneous microangiopathic hemolytic anemia, thrombocytopenia, and acute nephropathy in mother and child (clin. memo.) [Siegler] 991 (Oc)
Hemorrhage
corpus luteum hemorrhagicum, unusual complication of anticoagulant therapy (clin. memo.) [Shapiro] 523 (My)
Hemorrhage, Cerebral see Cerebral Hemorrhage
Hemorrhage, Gastrointestinal
hematemesis and melena in infant (clin. memo.) [Roth] 994 (Oc)

Heparin
heparin-precipitable cryoprecipitate in child with cold urticaria (clin. memo.) [Hurwitz] 797 (Au)
Hepatitis
outcome of, in children with acute leukemia [Malone] 584 (Je)
Hepatitis B
outcome of, in children with acute leukemia [Malone] 584 (Je)
Hepatolenticular Degeneration
trace elements in fetus and young infant, copper, manganese, selenium, and chromium [Shaw] 74 (Ja)
Hereditary Diseases
phenotypic variation in family with partial androgen insensitivity syndrome [Maes] 470 (My)
supranormal 25-hydroxyvitamin D and subnormal 1,25-dihydroxyvitamin D, role in X-linked hypophosphatemic rickets [Chesney] 140 (Fe)
TAR syndrome, dorsal pedal edema and excessive perspiration (clin. memo.) [Feingold] 895 (Se)
Hereditary Spinal Sclerosis see Friedreich's Ataxia
Hernia
liver herniation presenting as respiratory distress and cardiomegaly (clin. memo.) [Hofschire] 1091 (No)
Herpes Simplex
infection after needle aspiration of lymph node (clin. memo.) [Vikelidou] 88 (Ja)
Herpes Zoster
in early infancy (clin. memo.) [Dworsky] 618 (Je)
Herpes Zoster Virus see Varicella-Zoster Virus
Herpesvirus Varicellae see Varicella-Zoster Virus
Hine, Lewis W.
photograph, Boy 'Carrying in' Bottles in Glass Works, WVa, 960 (Oc)
photograph, Girl Shucking Oysters; Gulf Coast Canneries, 776 (Au)
Hirsutism
case of leprechaunism with severe hyperinsulinemia [Rosenberg] 170 (Fe)
History
editorial life in 14th century, 483 (My)
Hodgkin's Disease
as epitrochlear adenopathy (clin. memo.) [Berman] 319 (Mr)
Homovanillic Acid
CSF neurotransmitter studies, infant with ascorbic acid-responsive tyrosinemia [Stoerner] 492 (My)
Hospital Infections see Cross Infection
Hospital Nurseries see Nurseries, Hospital
Hospitalization see also Child, Hospitalized
are we in midst of a revolution? [Kennell] 303 (Mr)
rotavirus gastroenteritis in Washington, DC, area, incidence of cases resulting in [Rodriguez] 777 (Au)
Hospitalized Child see Child, Hospitalized
5-HTP see Hydroxytryptophan
Humerus
Hodgkin's disease as epitrochlear adenopathy (clin. memo.) [Berman] 319 (Mr)
Hyaline Membrane Disease
controlled study of inspiratory to expiratory ratio in its management by ventilator [Spahr] 373 (Ap)
Hydrocephalus
familial, increased amniotic fluid α-fetoprotein, and renal dysmorphology (clin. memo.) [Sinclair-Smith] 619 (Je)
intracranial hemorrhage in premature, predictive features and outcome [Kosmetatos] 855 (Se)
Hydrogen Peroxide
epidemiology of poisoning from drug products [Saracino] 763 (Au)
Hydrops see Edema
Hydroxyindoleacetic Acid
CSF neurotransmitter studies, infant with ascorbic acid-responsive tyrosinemia [Stoerner] 492 (My)
Hydroxytryptophan
and pyridoxine, effects in young children with Down's syndrome [Pueschel] 838 (Se)
Hyperactivity, Motor see Hyperkinesis
Hyperaldosteronism
Bartter's syndrome (letter) [Sann] (reply) [Arbus] 1097 (No)
treatment of Bartter's syndrome with indomethacin [Garin] 258 (Mr)
Hyperalimentation, Enteral see Enteral Feeding
Hypercorticism see Adrenal Gland Hyperfunction
Hyperglycemia
and sepsis in newborn (letter) [Kramer] (reply) [James] 427 (Ap)
Hyperinsulinism
severe, case of leprechaunism with [Rosenberg] 170 (Fe)
Hyperkinesis
hyperactivity, symptom complex or complex symptom? [Levine] 409 (Ap)
minimal brain dysfunction and [Carey] 926 (Oc)
new evidence on food additives and, critical analysis [Wender] 1122; in rebuttal [Swanson] 1124, [Weiss] 1126 (De)
nonstandard therapies in developmental disabilities [Golden] 487 (My)
Hypernatremia
hypernatremic dehydration of infancy, epidemiologic review [Paneth] 785 (Au), correction, 1096 (No)
Hypersensitivity, Delayed
diphtheria-tetanus skin testing, clinical value for [Kaufman] 479 (My)
Hypertelorism see Craniofacial Dysostosis
Hypertension
coarctation of aorta in children, late results after surgery [Beerman] 464 (My)
Hypertension, Pulmonary
pulmonary veno-occlusive disease appearing as acute, recurrent abdominal pain (clin. memo.) [Weinberg] 86 (Ja)
Hyperthyroidism
autoimmune thyroiditis with thyrotoxicosis eventuating in short interval hypothyroidism (clin. memo.) [Hahm] 206 (Fe)
complications of propranolol use in neonatal thyrotoxicosis (clin. memo.) [Newman] 707 (Jy)
hyperfunctioning thyroid nodules in children [Abe] 961 (Oc)
is propranolol alone really beneficial in neonatal thyrotoxicosis? bradycardia and hypoglycemia evoke doctrine of *primum non nocere* [Gardner] 819 (Se)
unilateral thyroid enlargement with (clin. memo.) [Leung] 890 (Se)
Hypertrichosis see Hirsutism
Hypogammaglobulinemia see Agammaglobulinemia
Hypoglycemia
and bradycardia evoke doctrine of *primum non nocere*, is propranolol alone really beneficial in neonatal thyrotoxicosis? [Gardner] 819 (Se)
metabolic studies in child with pancreatic insulinoma [Ginsberg-Fellner] 64 (Ja)
nonstandard therapies in developmental disabilities [Golden] 487 (My)
Hyponatremia
Bartter's syndrome (letter) [Sann] (reply) [Arbus] 1097 (No)
symptomatic, in nephrotic syndrome (clin. memo.) [Hurley] 204 (Fe), correction, 502 (My)
Hyponatremia—Continued
Hypoparathyroidism
serum 1,25-dihydroxyvitamin D levels in normal children and in vitamin D disorders [Chesney] 135 (Fe)
Hypophosphatemia, Familial
supranormal 25-hydroxyvitamin D and subnormal 1,25-dihydroxyvitamin D, role in X-linked hypophosphatemic rickets [Chesney] 140 (Fe)
Hypopituitarism
topically applied testosterone and phallic growth, effect in male children with microphallus and [Ben-Galim] 296 (Mr)
Hypoproteinemia see Protein-Losing Enteropathies
Hypotension
group B streptococcal disease, diagnosis with use of antigen detection, Gram's stain, and presence of apnea and [Ingram] 754 (Au)
Hypothyroidism
cardiomyopathy of, revisited, are children different than adults? [Santos] 547 (Je)
congenital, elevated threshold for thyrotropin suppression in [Schultz] 19 (Ja)
elevated serum concentrations of triiodothyronine in, values for patients receiving USP thyroid [Penny] 16 (Ja)
multicystic ovaries detected by sonography in children with [Lindsay] 588 (Je)
primary, cardiac function in [Hayford] 556 (Je)
progress and little gray pill [Hayles] 13 (Ja)
short interval, autoimmune thyroiditis with thyrotoxicosis eventuating in (clin. memo.) [Hahm] 206 (Fe)
Hypoxemia see Anoxemia
Hypoxia see Anoxia

I

Idiopathic Hypercatabolic Hypoproteinemia see Protein-Losing Enteropathies

Intestinal Mucosa
enteric duplication cyst, picture of month [Gellis, Pierce] 985 (Oc)

Intestinal Obstruction
milk curd, mimicking necrotizing enterocolitis (clin. memo.) [Berkowitz] 989 (Oc)
Intestinal Secretions see Gastrointestinal Hormones
Intestine, Small
length in infants and children [Siebert] 593 (Je), enlongated in prune-belly syndrome (letter) [Miller] (reply) [Siebert] 1182 (De)
Intrauterine Diagnosis see Prenatal Diagnosis
Intubation
nasal deformities in neonates treated with nasal continuous positive airway pressure and nasal endotracheal tubes [Gowdar] 954 (Oc)
Intubation, Gastrointestinal see Enteral Feeding
Intubation, Intratracheal
esophageal perforations in premature infants, comments on diagnosis [Clarke] 367 (Ap)
use of side-hole endotracheal tube adapter for tracheal aspiration [Zmora] 250 (Mr)
Iron
absorption from human milk, inhibition by baby food [Oski] 459 (My)
absorption, inhibition of, by certain foods [Dallman] 453 (My)
acute poisoning, review [Robotham] 875 (Se)
phosphate poisoning complicating treatment for ingestion of [Geffner] 509 (My)
Ischium
traumatic ischial apophyseolysis, radiological case of month [Young, Tan] 885 (Se)
Islet Cell Tumor
metabolic studies in child with pancreatic insulinoma [Ginsberg-Fellner] 64 (Ja)
Isoetharine
management of acute asthma in childhood, randomized evaluation of β-adrenergic agents [Schwartz] 474 (My)
Isomerases
uridine diphosphate galactose 4-epimerase deficiency (clin. memo.) [Ichiba] 995 (Oc)
Isoniazed
acute poisoning in childhood [Miller] 290 (Mr)
Isopropyl Alcohol see Alcohol, Propyl

J

Jaundice, Cholestatic see Cholestasis
Jaundice, Hemolytic see Anemia, Hemolytic
Jaundice, Obstructive see Cholestasis
Jurisprudence
trauma and child abuse, importance of medical record [Solomons] 503 (My)

K

Käsebier, Gertrude
Road to Rome, photograph, 1902, 642 (Jy)
Karyotyping
live-born triploid (clin. memo.) [Fraikor] 988 (Oc)
triplo-X and Down's syndrome (letter) [Yeatman] (reply) [Gardner] 527 (My)
Kawasaki Disease
acute febrile mucocutaneous lymph node syndrome [Yanagihara] 603 (Je)
Ketone Bodies
elimination of acetone bodies during infectious fevers, *60 Years Ago in AJDC*, 158 (Fe)
Kidney
increased amniotic fluid α-fetoprotein, familial hydrocephalus, and renal dysmorphology (clin. memo.) [Sinclair-Smith] 619 (Je)
Kidney Diseases
simultaneous microangiopathic hemolytic anemia, thrombocytopenia, and acute nephropathy in mother and child (clin. memo.) [Siegler] 991 (Oc)
Kidney Failure, Acute
Reye's syndrome associated with disseminated intravascular coagulation and (letter) [Muntean] 999 (Oc)
Kidney Failure, Chronic
moderate, encephalopathy in young children with [Bale] 581 (Je)
Kidney Transplantation
macrocytosis and pure RBC anemia caused by azathioprine [DeClerck] 377 (Ap)
Kidney Tubular, Necrosis, Acute see Kidney Failure, Acute
Kinky Hair Syndrome
copper ligands in human milk, vehicle for copper supplementation in Menkes' disease? (letter) [Lönnerdal] 802 (Au)
trace elements in fetus and young infant, copper, manganese, selenium, and chromium [Shaw] 74 (Ja)
Klebsiella aerogenes see Klebsiella pneumoniae
Klebsiella pneumoniae
chronic otitis media in children, microbiological studies [Brook] 564 (Je)

L

Labor
alternative birthing center, one family's experience [Butzen] 348 (Ap)
Labor Presentation
'breech head' with brow presentation (clin. memo.) [Wassman] 994 (Oc)
Lactase
elevated meconium activity, use as screening test for cystic fibrosis [Berry] 930 (Oc)
Lambliasis see Giardiasis
Larva Migrans, Visceral
mitogenic response to *Toxocara* antigen and chemotactic defect in [Caldwell] 845 (Se)
Larynx
laryngeal mucous gland excess in victims of sudden infant death [Fink] 144 (Fe)
Learning Disorders
hearing loss and learning disability (letter) [Hersher] (reply) [Zinkus] 94 (Ja)
nonstandard therapies in developmental disabilities [Golden] 487 (My)
Leprechaunism
case with severe hyperinsulinemia [Rosenberg] 170 (Fe)
Lethal Midline Granuloma see Granuloma, Lethal Midline
Leukemia
acute, outcome of hepatitis in children with [Malone] 584 (Je)
fatal, congenital leukemoid reaction followed by, case with Down's syndrome [Lin] 939 (Oc)
prevention of pneumocystis pneumonia, use of continuous sulfamethoxazole-trimethoprim therapy [Harris] 35 (Ja)
Leukemia, Granulocytic see Leukemia, Myelocytic
Leukemia, Lymphoblastic
acute, spontaneous splenic rupture in, successful nonoperative management (clin. memo.) [Soorya] 201 (Fe)
childhood acute, pneumonia during therapy for [Siegel] 28 (Ja)
pneumatosis intestinalis, occurrence in immunologically compromised child [Kleinman] 1149 (De)
Leukemia, Lymphocytic, Acute see Leukemia, Lymphoblastic
Leukemia, Myelocytic
juvenile chronic granulocytic leukemia, emphasis on cutaneous manifestations and underlying neurofibromatosis [Mays] 654 (Jy)
Leukemia, Myelocytic, Chronic see Leukemia, Myelocytic
Leukemia, Myelogenous, Chronic see Leukemia, Myelocytic
Leukemia, Naegeli Type see Leukemia, Myelocytic
Leukemoid Reaction
congenital, followed by fatal leukemia, case with Down's syndrome [Lin] 939 (Oc)
Leukocytes
transient "lazy-leukocyte" syndrome during infancy [Yoda] 467 (My)
Leukocytes, Polymorphonuclear see Neutrophils
Levocardia see Heart Defects, Congenital
Levothyroxine
elevated serum concentrations of triiodothyronine in hypothyroid patients, values for patients receiving USP thyroid [Penny] 16 (Ja)
progress and little gray pill [Hayles] 13 (Ja)
Lidocaine
ingestion (clin. memo.) [Sakai] 323 (Mr)
Lignac-Fanconi Syndrome see Fanconi Syndrome
Limbs see Extremities
Lip
lip pits, cleft lip and/or palate, and congenital heart disease [Pauli] 293 (Mr)
Lipoma
retroperitoneal, in child, radiological case of month [Young, Severson] 83 (Ja)
Lipoproteins, LDL
essential fatty acids revisited [Friedman] 397 (Ap)
Lithium Carbonate
Ebstein's anomaly of tricuspid valve associated with prenatal exposure to (clin. memo.) [Park] 703 (Jy)
Liver
cimetidine in pregnancy, apparent transient impairment of, in newborn (clin. memo.) [Glade] 87 (Ja)
herniation presenting as respiratory distress and cardiomegaly (clin. memo.) [Hofschire] 1091 (No)
Liver Diseases
infantile cholestatic (letters) [Harris] 623 (Je), 801 (Au), (reply) [Rosenthal] 802 (Au)
Longevity
mortality and sex difference (letter) [Waldron] 999 (Oc)
Low Density Lipoproteins see Lipoproteins, LDL
Lumbar Puncture see Spinal Puncture
Lung
acute pulmonary exacerbations in cystic fibrosis, double-blind trial of tobramycin and placebo [Wientzen] 1134 (De)
anomalous apical bronchus of right upper lobe, radiological case of month [Young, Fujioka] 615 (Je)
early-onset sepsis and pneumonia observed as respiratory distress syndrome, assessment of maturity of [Jacob] 766 (Au)
fluid administration and bronchopulmonary dysplasia, lack of association [Spahr] 958 (Oc)
intravenous aminophylline in cystic fibrosis, pharmacokinetics and effect on function of [Larsen] 1143 (De)
open biopsy specimen, congenital miliary tuberculosis proved by, successfully treated (clin. memo.) [Stallworth] 320 (Mr)
prostaglandins [Olley] 688 (Jy)
Lung Diseases see also Pulmonary Heart Disease
infectious mononucleosis complicated by severe *Mycoplasma pneumoniae* infection [Dearth] 744 (Au)
Lymph Nodes
herpes simplex infection after needle aspiration of (clin. memo.) [Vikelidou] 88 (Ja)
Hodgkin's disease as epitrochlear adenopathy

Lymph Nodes—Continued
(clin. memo.) [Berman] 319 (Mr)
Lymphangiectasis, Intestinal see Protein-Losing Enteropathies
Lymphangioma
cystic, hygroma, diagnosis by ultrasound, radiological case of month [Young, Haimovici] 311 (Mr); genetic implications (letter) [Rutledge] 999, (reply) [Haimovici] 1000 (Oc)
Lymphatic Diseases see also Leukemia, Lymphoblastic
acute febrile mucocutaneous lymph node syndrome [Yanagihara] 603 (Je)
Lymphocyte Mitogenic Factor see Mitogenic Factor
Lymphocytes
measles-specific reactivity and serum antibody in subjects with different measles histories [Krause] 567 (Je)
Lymphokines
mitogenic response to *Toxocara* antigen and chemotactic defect in visceral larva migrans [Caldwell] 845 (Se)

M

Macrobiotics, Zen see Zen Macrobiotics
Malnutrition see Nutrition Disorders
Manganese
trace elements in fetus and young infant [Shaw] 74 (Ja)
Manometry
esophageal, compared to string test for gastroesophageal reflux [Liebman] 755 (Au)
Marasmus see Protein-Calorie Malnutrition
Marden-Walker Syndrome
sixth case (letter) [Fitch] 93 (Ja)
Mass Screening
elevated meconium lactase activity, use as screening test for cystic fibrosis [Berry] 930 (Oc)
incidence of meconium abnormalities in newborn infants with cystic fibrosis [Rosenstein] 72 (Ja)
newborn, in New York State, 498 (My)
of newborns for sickle cell anemia (letters) [Smith, Grover] 1180, [Detter, Rao] 1181, (replies) [Rubin] 1181, [Miller] 1182 (De)
screening of newborns for cystic fibrosis [Gibson] 925 (Oc)
Maternal-Fetal Exchange see also Abnormalities, Drug-Induced
cimetidine in pregnancy, apparent transient liver impairment in newborn (clin. memo.) [Glade] 87 (Ja)
Clostridium infection in mother and infant (clin. memo.) [Chaney] 1175 (De)
congenital miliary tuberculosis proved by open lung biopsy specimen and successfully treated (clin. memo.) [Stallworth] 320 (Mr)
congenital toxoplasmosis [Stagno] 635 (Jy)
early growth patterns of methadone-addicted infants [Chasnoff] 1049 (No)
herpes zoster in early infancy (clin. memo.) [Dworsky] 618 (Je)
immunologic maturation in infant born to mother with agammaglobulinemia [Kobayashi] 942 (Oc)
infants potentially at risk for congenital toxoplasmosis [Stray-Pedersen] 638 (Jy)
neonatal death associated with acute transplacental ethanol intoxication (clin. memo.) [Jung] 419 (Ap)
Measles
measles-specific lymphocyte reactivity and serum antibody in subjects with different measles histories [Krause] 567 (Je)
Measles Vaccine
commentary on immunization [Shaw] 130 (Fe)
measles-specific lymphocyte reactivity and serum antibody in subjects with different measles histories [Krause] 567 (Je)
recordkeeping and physician certification of immunization status (clin. memo.) [Faust] 203 (Fe)
Meconium
abnormalities in newborn infants with cystic fibrosis, incidence of [Rosenstein] 72 (Ja)
elevated lactase activity, use as screening test for cystic fibrosis [Berry] 930 (Oc)
Median Nerve see Carpal Tunnel Syndrome
Medical Audit
trauma and child abuse, importance of medical record [Solomons] 503 (My)
Medical Devices see Equipment and Supplies
Medical Records
are we in midst of a revolution? [Kennell] 303 (Mr)
pediatrics and record-keeping (letter) [Sparling] (reply) [Margolis] 326 (Mr)
recordkeeping and physician certification of measles immunization status (clin. memo.) [Faust] 203 (Fe)
trauma and child abuse, importance of [Solomons] 503 (My)
Megavitamin Therapy see Orthomolecular Therapy
Melena
and hematemesis in infant (clin. memo.) [Roth] 994 (Oc)
Menarche
menarchal determinants in cystic fibrosis [Moshang] 1139 (De)
Meningitis
anaerobic bacteremia in children [Brook] 1052 (No)
mumps, local immunity in [Morishima] 1060 (No)
Meningitis, Tuberculous see Tuberculosis, Meningeal
Meningitis, Viral
acute coxsackie B4, CSF eosinophilia during (clin. memo.) [Chesney] 703 (Jy)
Meningocele
occult anterior sacral [Sumner] 385 (Ap)
Meningococcal Infections
fulminant neonatal meningococcemia [Clegg] 354 (Ap)
severe, caused by serogroups X and Z (clin. memo.) [Ryan] 1173 (De)
Meningococcus see Neisseria meningitidis
Menkes Syndrome see Kinky Hair Syndrome
Menstruation
menarchal determinants in cystic fibrosis [Moshang] 1139 (De)
Mental Deficiency see Mental Retardation
Mental Retardation see also Chromosome Abnormalities
argininosuccinicaciduria, hair abnormality revisited (clin. memo.) [Potter] 1095 (No)
encephalopathy in young children with moderate chronic renal failure [Bale] 581 (Je)
syndrome of infantile CNS degeneration [Holmes] 262 (Mr)
Mercaptopurine
nasal polymorphic reticulosis in child [Houghton] 387 (Ap)
Metabolism
CNS manifestations of hemolytic-uremic syndrome, relationship to metabolic alterations and prognosis [Bale] 869 (Se)
metabolic studies in child with pancreatic insulinoma [Ginsberg-Fellner] 64 (Ja)
Metatarsus
cleidocranial dysostosis, severe micrognathism, bilateral absence of thumbs and first metatarsal bone, and distal aphalangia, new genetic syndrome [Yunis] 649 (Jy)
Methadone
early growth patterns of infants addicted to [Chasnoff] 1049 (No)
Methotrexate
nasal polymorphic reticulosis in child [Houghton] 387 (Ap)
Micrococcus pyogenes see Staphylococcus aureus
Micrognathism
severe, cleidocranial dysostosis, bilateral absence of thumbs and first metatarsal bone, and distal aphalangia, new genetic syndrome [Yunis] 649 (Jy)
Milk
milk curd obstruction mimicking necrotizing enterocolitis (clin. memo.) [Berkowitz] 989 (Oc)
recurrent abdominal pain (letter) [Crook] 326, (reply) [Stickler] 327 (Mr)
Milk, Human
cells and aqueous component of (letter) [Khan] (reply) [France] 1002 (Oc)
copper ligands in, vehicle for copper supplementation in Menkes' disease? (letter) [Lönnerdal] 802 (Au)
inhibition of iron absorption by certain foods [Dallman] 453 (My)
iron absorption from, inhibition by baby food [Oski] 459 (My)
Minerals
nonstandard therapies in developmental disabilities [Golden] 487 (My)
vegetarianism in children [MacLean] 513 (My)
Minimal Brain Dysfunction
and hyperkinesis [Carey] 926 (Oc)
Mitogenic Factor
mitogenic response to *Toxocara* antigen and chemotactic defect in visceral larva migrans [Caldwell] 845 (Se)
Miyagawanella Infections see Chlamydia Infections
Molybdenum
metabolism (letter) [Beemer] 1097 (reply) [Shaw] 1098 (No)
Mongolism see Down's Syndrome
Mortality
and sex difference (letter) [Waldron] 999 (Oc)
Mother-Child Relations
body contact, are we in midst of a revolution? [Kennell] 303 (Mr)
women who abuse their children, implications for pediatric practice [Rosen] 947 (Oc)
Motor Activity
encephalopathy in young children with moderate chronic renal failure [Bale] 581 (Je)
syndrome of infantile CNS degeneration [Holmes] 262 (Mr)
Mucocutaneous Lymph Node Syndrome see Lymphatic Diseases
Mucous Membrane
laryngeal mucous gland excess in victims of sudden infant death [Fink] 144 (Fe)
Mucoviscidosis see Cystic Fibrosis
Mumps
meningitis, local immunity in [Morishima] 1060 (No)
Mumps Vaccine
commentary on immunization [Shaw] 130 (Fe)
Munchausen Syndrome
case report in pediatric age group (clin. memo.) [Paperny] 794 (Au)
Muscle Dystonia
promethazine-induced acute dystonic reactions (clin. memo.) [Darwish] 990 (Oc)
Muscle Tonus
Marden-Walker syndrome (letter) [Fitch] 93 (Ja)
syndrome of infantile CNS degeneration [Holmes] 262 (Mr)
Muscles
juvenile aponeurotic fibroma, radiological case of month [Young, Lowell] 195 (Fe)
Mycobacterium tuberculosis
tuberculin-negative tuberculosis, persistently

Mycobacterium tuberculosis—Continued
negative tuberculin reactions among children with culture positive for [Steiner] 747 (Au)
Mycoplasma Infections
severe *M pneumoniae*, infectious mononucleosis complicated by [Dearth] 744 (Au)
Myelography
isotopic cisternography in tuberculous meningitis of childhood [Özdirim] 572 (Je)
occult anterior sacral meningocele [Sumner] 385 (Ap)
Myocardial Infarction
in neonate with normal heart and coronary arteries [Kilbride] 759 (Au)
Myocardium
Friedreich's ataxia with acute cardiomyopathy [Berg] 390 (Ap)
Myoclonus
nonketotic hyperglycinemia, effects of therapy with strychnine [Warburton] 273 (Mr)
Myodystrophia Fetalis Deformans see Arthrogryposis

N

Nafcillin
cutaneous necrosis associated with intravenous therapy [Tilden] 1046 (No)
Naloxone
underdosage after narcotic poisoning [Moore] 156 (Fe)
Narcotics
naloxone, underdosage after narcotic poisoning [Moore] 156 (Fe)
Nasal Mucosa
infant, adherence of *Staphylococcus aureus* to cells of (clin. memo.) [Aly] 522 (My)
Nasal Septum
nasal polymorphic reticulosis in child [Houghton] 387 (Ap)
Nasopharyngitis see Pharyngitis
National Health Service, British see State Medicine
Nebcina see Tobramycin
Neck Neoplasms see Head and Neck Neoplasms
Necrosis
cutaneous, associated with intravenous nafcillin therapy [Tilden] 1046 (No)
feeding and necrotizing enterocolitis [Goldman] 553 (Je)
necrotizing enterocolitis (letter) [Goldman] (reply) [Guinan] 207 (Fe)
necrotizing enterocolitis and enteral feeding, is too much just too much? [Eidelman] 545 (Je)
necrotizing fasciitis after neonatal circumcision [Woodside] 301 (Mr), (letter) [Katz] (reply) [Woodside] 1098 (No)
Necrotizing Arteritis see Periarteritis Nodosa
Needles
improved needle for sinus therapy, *60 Years Ago in AJDC*, 327 (Mr)
Neisseria meningitidis
fulminant neonatal meningococcemia [Clegg] 354 (Ap)
severe meningococcal disease caused by serogroups X and Z (clin. memo.) [Ryan] 1173 (De)
Neoplasms
bacteremias due to *Haemophilus influenzae* and *Streptococcus pneumoniae*, occurrence and course in children with cancer [Siber] 668 (Jy)
chemoprophylaxis for *Pneumocystis carinii* pneumonitis, outcome of unstructured delivery [Wilber] 643 (Jy)
functioning tumors [Voorhess] 14 (Ja)
prevention of pneumocystis pneumonia, use of continuous sulfamethoxazole-trimethoprim therapy [Harris] 35 (Ja)
Staphylococcus aureus sepsis in childhood malignancy [Miser] 831 (Se)
Neoplasms—Continued
vasoactive intestinal peptide secreting tumors of childhood [Kaplan] 21 (Ja)
Neoplasms, Multiple Primary see Adenomatosis, Familial Endocrine
Neoplasms, Nervous Tissue
cerebellar ataxia, opsoclonus, and occult neural crest tumor, abdominal computerized tomography in diagnosis [Kinast] 1057 (No)
Nephritis
changes in zinc metabolism during course of nephrotic syndrome [Reimold] 46 (Ja)
Nephrosis
changes in zinc metabolism during course of nephrotic syndrome [Reimold] 46 (Ja)
Nephrotic Syndrome
changes in zinc metabolism during course of [Reimold] 46 (Ja)
symptomatic hyponatremia in (clin. memo.) [Hurley] 204 (Fe), correction, 502 (My)
Nerve Transmitter Substances see Neuroregulators
Neural Crest
cerebellar ataxia, opsoclonus, and occult tumor of, abdominal computerized tomography in diagnosis [Kinast] 1057 (No)
Neuritis
polyneuritic syndrome resembling pellegra-acrodynia(?) seen in very young children, *60 Years Ago in AJDC*, 1064 (No)
Neurofibromatosis
underlying juvenile chronic granulocytic leukemia, emphasis on cutaneous manifestations and [Mays] 654 (Jy)
with congenital glaucoma and buphthalmos in newborn [Satran] 182 (Fe)
Neurohumors see Neuroregulators
Neurologic Manifestations
CNS, of hemolytic-uremic syndrome, relationship to metabolic alterations and prognosis [Bale] 869 (Se)
computerized tomography to define CNS involvement in congenital cytomegalovirus infection (clin. memo.) [Anders] 795 (Au)
encephalopathy in young children with moderate chronic renal failure [Bale] 581 (Je)
Neuroregulators
CSF neurotransmitter studies, infant with ascorbic acid-responsive tyrosinemia [Stoerner] 492 (My)
Neurotransmitters see Neuroregulators
Neutropenia see Agranulocytosis
Neutrophils
transient "lazy-leukocyte" syndrome during infancy [Yoda] 467 (My)
Nevus, Pigmented
Ota's nevus picture of month [Gellis, Fikar] 1083 (No)
News Media Relations see Public Relations
Niacinamide see Nicotinamide
Nicotinamide
accidental ingestion of Vacor rodenticide (PNU), symptoms and sequelae [Johnson] 161 (Fe), (letter) [LeWitt] 1178 (De)
Nomenclature
triplo-X and Down's syndrome (letter) [Yeatman] (reply) [Gardner] 527 (My)
Nose
nasal deformities in neonates treated with nasal continuous positive airway pressure and nasal endotracheal tubes [Gowdar] 954 (Oc)
nasal polymorphic reticulosis in child [Houghton] 387 (Ap)
Nose Neoplasms
nasal polymorphic reticulosis in child [Houghton] 387 (Ap)
Nosocomial Infections see Cross Infection
Nurseries, Hospital
necrotizing enterocolitis, epidemic following outbreak of *Enterobacter cloacae* type 3305573 in neonatal intensive care unit [Powell] 1152 (De)
Nurseries, Hospital—Continued
special care, nosocomial transmission of bacteriophage type 7/11/12 group B streptococci in [Boyer] 964 (Oc)
Nutrition
diets for children and adolescents that meet dietary goals [Dwyer] 1073 (No)
lesson in, habits of WH Welch and OT Avery [Dubos] 583 (Je)
Nutrition Disorders
cell-mediated immune defects and infection, study of malnourished hospitalized children [Carney] 824 (Se)
infantile nutritional copper deficiency, radiological case of month [Young, Bennani-Smires] 1155 (De)
nutritional osteomalacia (letter) [Elinson] 427 (Ap)
"teach a man to fish" (Chinese proverb) [Sumpter] 1025 (No)
vegetarianism in children [MacLean] 513 (My)

O

Obstetrics
alternative birthing center, one family's experience [Butzen] 348 (Ap)
Occult Blood see Melena
Ocular Herpes Zoster Virus see Varicella-Zoster Virus
Oculomotor Paralysis see Ophthalmoplegia
Oncolysis see Neoplasms
Ophthalmoplegia
syndrome of infantile CNS degeneration [Holmes] 262 (Mr)
Opsoclonus
cerebellar ataxia, occult neural crest tumor and, abdominal computerized tomography in diagnosis [Kinast] 1057 (No)
Opsonins
breast-feeding and *Salmonella* infection [French] 147 (Fe)
Optic Atrophy
syndrome of infantile CNS degeneration [Holmes] 262 (Mr)
Optometry
nonstandard therapies in developmental disabilities [Golden] 487 (My)
Orthomolecular Therapy
nonstandard therapies in developmental disabilities [Golden] 487 (My)
Osteolysis see Bone Resorption
Osteomalacia
nutritional (letter) [Elinson] 427 (Ap)
Osteomyelitis
acute, 'normal' technetium bone scans in patients with [Berkowitz] 828 (Se)
falsely normal radionuclide scans for [Fleisher] 499 (My)
streptococcal neonatal (letter) [Lai] 711 (Jy)
Osteopoikilosis see Osteosclerosis
Osteoporosis
infantile nutritional copper deficiency, radiological case of month [Young, Bennani-Smires] 1155 (De)
Osteosclerosis
osteopoikilosis, familial documentation, radiological case of month [Young, Gershman] 415 (Ap)
Otitis Media
bilateral, disparate cultures of middle ear fluids, results from children with [Pelton] 951 (Oc)
chronic, in children, microbiological studies [Brook] 564 (Je)
hearing loss and learning disability (letter) [Hersher] (reply) [Zinkus] 94 (Ja)
in children, cefaclor in treatment of [McLinn] 560 (Je)
Ovary
multicystic ovaries detected by sonography in

Ovary—Continued
children with hypothyroidism [Lindsay] 588 (Je)
Oxycephaly see Craniosynostoses
Oxygen Consumption
effect of circumcision on transcutaneous Po_2 in term infants [Rawlings] 676 (Jy)
Oxygen Deficiency see Anoxia

P

Pain
effect of circumcision on transcutaneous Po_2 in term infants [Rawlings] 676 (Jy)
Pancreatic Cystic Fibrosis see Cystic Fibrosis
Pancreatic Diseases see Hyperinsulinism
Pancreatic Neoplasms
metabolic studies in child with insulinoma [Ginsberg-Fellner] 64 (Ja)
Pancreatitis
Reye's syndrome and (letter) [Gilboa] 903 (Se)
Pancuronium
and abnormal abdominal roentgenograms [Dillard] 821 (Se)
Paradoxical Sleep see Sleep, REM
Patient Education
circumcision and (letter) [Gorske] 527 (My)
Patients' Visitors see Visitors to Patients
Patterning
nonstandard therapies in developmental disabilities [Golden] 487 (My)
Pediatrics
and record-keeping (letter) [Sparling] (reply) [Margolis] 326 (Mr)
are we in midst of a revolution? [Kennell] 303 (Mr)
fate of Special Care Baby Unit in London (letter from abroad) [Barrie] 431 (Ap)
many advantages of direct microfocus roentgenographic magnification in pediatric radiology, portable x-ray machine with uniquely different x-ray tube [Brodeur] 245 (Mr)
Pellagra
polyneuritic syndrome resembling pellegra-acrodynia(?) seen in very young children, *60 Years Ago in AJDC*, 1064 (No)
Pelvis
streptococcal neonatal osteomyelitis (letter) [Lai] 711 (Jy)
Penicillin V Potassium
cefaclor in treatment of otitis media and pharyngitis in children compared with [McLinn] 560 (Je)
Penicillins
epidemiology of poisoning from drug products [Saracino] 763 (Au)
Penile Neoplasms
circumcision and risk of, life-table analysis [Kochen] 484 (My)
Penis see also Circumcision
phenotypic variation in family with partial androgen insensitivity syndrome [Maes] 470 (My)
topically applied testosterone and phallic growth, effect in male children with hypopituitarism and microphallus [Ben-Galim] 296 (Mr)
Peptides
functioning tumors [Voorhess] 14 (Ja)
insulin biosynthesis and C-peptide, practical applications from basic research [Sperling] 1119 (De)
urine C-peptide, β-cell function, and insulin requirement [Rappaport] 1129 (De)
vasoactive intestinal peptide secreting tumors of childhood [Kaplan] 21 (Ja)
Percordan
epidemiology of poisoning from drug products [Saracino] 763 (Au)
Periarteritis Nodosa
acute febrile mucocutaneous lymph node syndrome [Yanagihara] 603 (Je)
Pericardial Effusion
cardiac function in primary hypothyroidism [Hayford] 556 (Je)
Pericardium
intrapericardial teratoma, new and treatable cause of hydrops fetalis (clin. memo.) [Banfield] 1174 (De)
Periodicals
critical academic mass [Bergstrom] 129 (Fe)
Periosteum
infantile nutritional copper deficiency, radiological case of month [Young, Bennani-Smires] 1155 (De)
Peritonitis
pneumococcus, in infancy and early childhood, *60 Years Ago in AJDC*, 1045 (No)
Pertussis see Whooping Cough
Pertussis Vaccine
commentary on immunization [Shaw] 130 (Fe)
Petechiae see Purpura
Phagocytosis
breast-feeding and *Salmonella* infection [France] 147 (Fe)
Pharyngitis
in children, cefaclor in treatment of [McLinn] 560 (Je)
metastatic complications of *Fusobacterium necrophorus* sepsis, 2 cases of Lemierre's postanginal septicemia [Vogel] 356 (Ap)
Phencyclidine
epidemiology of poisoning from drug products [Saracino] 763 (Au)
Phenergan see Promethazine
Phenotype
infantile cholestatic liver disease (letters) [Harris] 623 (Je), 801 (Au), (reply) [Rosenthal] 802 (Au)
phenotypic variation in family with partial androgen insensitivity syndrome [Maes] 470 (My)
Phenylalanine
diagnosis of phenylketonuria, Collaborative Study of Children Treated for Phenylketonuria [O'Flynn] 769 (Au)
Phenylketonuria
diagnosis of, Collaborative Study of Children Treated for Phenylketonuria [O'Flynn] 769 (Au)
Phlegmasia Alba Dolens see Thrombophlebitis
Phobias
fever, misconceptions of parents about fevers [Schmitt] 176 (Fe), (letter) [Cohen] 1001 (Oc)
Phosphates
poisoning complicating treatment for iron ingestion [Geffner] 509 (My)
supranormal 25-hydroxyvitamin D and subnormal 1,25-dihydroxyvitamin D, role in X-linked hypophosphatemic rickets [Chesney] 140 (Fe)
Phospholipids
essential fatty acids revisited [Friedman] 397 (Ap)
Photography
Boy 'Carrying in' Bottles in Glass Works, WVa, Lewis W. Hine, 960 (Oc)
Girl Shucking Oysters; Gulf Coast Canneries, Lewis W. Hine, 776 (Au)
Miss Alice Pleasance Liddell, Lewis Carroll, 823 (Se)
'Mother Goose of '93,' Mrs. N. Gray Bartlett, 1166 (De)
Ring Toss, Clarence H. White, 1099 (No)
Road to Rome, Gertrude Käsebier, 1902, 642 (Jy)
Physical Education and Training
injuries in high school physical education classes [Austin] 456 (My)
PICTURE OF MONTH
enteric duplication cyst [Gellis, Pierce] 985 (Oc)
hemifacial atrophy (Romberg's syndrome) [Gellis, Tirosh] 883 (Se)
Marcus Gunn phenomenon [Gellis, Eckerd] 783 (Au)
metaphyseal chondrodysplasia, Schmid type [Gellis, Pavone] 699 (Jy)
Ota's nevus [Gellis, Fikar] 1083 (No)
Pigmentation Disorders
focal cerebral atrophy in incontinentia pigmenti achromians (clin. memo.) [Donat] 709 (Jy)
Rothmund-Thomson syndrome with severe dwarfism [Hall] 165 (Fe)
Pilonidal Cyst
abscess in children, aerobic and anaerobic bacteriology of [Brook] 679 (Jy)
Pink Disease see Acrodynia
Placebos
acute pulmonary exacerbations in cystic fibrosis, double-blind trial of tobramycin therapy and [Wientzen] 1134 (De)
new evidence on food additives and hyperkinesis, critical analysis [Wender] 1122; in rebuttal [Swanson] 1124, [Weiss] 1126 (De)
Placenta see Maternal-Fetal Exchange
Platelets see Blood Platelets
Pleural Effusion
pneumococcal empyema, outcome of medical management [Murphy] 659 (Jy)
Pleurodynia Virus see Coxsackie B Viruses
Pleuropneumonia, Contagious see Mycoplasma Infections
Pneumatosis Cystoides Intestinalis
occurrence in immunologically compromised child [Kleinman] 1149 (De)
Pneumococcal Infections
empyema, outcome of medical management [Murphy] 659 (Jy)
peritonitis in infancy and early childhood, *60 Years Ago in AJDC*, 1045 (No)
Pneumococcus see Streptococcus pneumoniae
Pneumocystis carinii Pneumonia see Pneumonia, Interstitial Plasma Cell
Pneumonia
during therapy for childhood acute lymphoblastic leukemia [Siegel] 28 (Ja)
early-onset sepsis and, observed as respiratory distress syndrome, assessment of lung maturity [Jacob] 766 (Au)
giant cell, radiological case of month [Young, Ross] 511 (My)
hydrops of gallbladder (clin. memo.) [Neu] 891 (Se)
severe influenza A, in infancy, amantadine for (clin. memo.) [Fishaut] 321 (Mr)
severe neonatal chlamydial pneumonitis (clin. memo.) [Sagy] 89 (Ja)
study of pneumonia in infancy and childhood during recent epidemics [Heiman] 740 (Au)
water retention in, *60 Years Ago in AJDC*, 478 (My)
Pneumonia, Aspiration
foreign body in airway, review of 200 cases [Blazer] 68 (Ja)
migration of inflorescence, complications of grass head aspiration (clin. memo.) [Steele] 704 (Jy)
Pneumonia, Interstitial Plasma Cell
chemoprophylaxis for *Pneumocystis carinii* pneumonitis, outcome of unstructured delivery [Wilber] 643 (Jy)
during therapy for childhood acute lymphoblastic leukemia [Siegel] 28 (Ja)
prevention of *Pneumocystis* pneumonia, use of continuous sulfamethoxazole-trimethoprim therapy [Harris] 35 (Ja)
PNU (Vacor) see Rodenticides
Poikiloderma Congenitale
Rothmund-Thomson syndrome with severe dwarfism [Hall] 165 (Fe)
Poisoning
accidental ingestion of Vacor rodenticide (PNU), symptoms and sequelae [Johnson] 161 (Fe),

Poisoning—Continued
(letter) [LeWitt] 1178 (De)
acute iron, review [Robotham] 875 (Se)
acute isoniazid, in childhood [Miller] 290 (Mr)
doxepin, in child (clin. memo.) [Walter] 202 (Fe)
from drug products, epidemiology of [Saracino] 763 (Au)
narcotic, underdosage of naloxone after [Moore] 156 (Fe)
• phosphate, complicating treatment for iron ingestion [Geffner] 509 (My)
Poliovirus Vaccine
commentary on immunization [Shaw] 130 (Fe)
Polyarteritis Nodosa see Periarteritis Nodosa
Polysomy X Syndrome
triplo-X and Down's syndrome (letter) [Yeatman] (reply) [Gardner] 527 (My)
Porencephaly
from periventricular intracerebral hemorrhage in premature infant [Pasternak] 673 (Jy)
Positive Pressure Respiration
nasal deformities in neonates treated with nasal continuous positive airway pressure and nasal endotracheal tubes [Gowdar] 954 (Oc)
systemic air embolism secondary to respiratory therapy, radiological case of month [Young, Kogutt] 983 (Oc)
use of side-hole endotracheal tube adapter for tracheal aspiration [Zmora] 250 (Mr)
Postoperative Complications
coarctation of aorta in children, late results after surgery [Beerman] 464 (My)
Posture
bodily mechanics, relation to cyclic vomiting and other obscure intestinal conditions, *60 Years Ago in AJDC*, 907 (Se)
Prednisone
subacute thyroiditis in 4½-year-old girl (clin. memo.) [Buchta] 1090 (No)
Pregnancy
cimetidine in, apparent transient liver impairment in newborn (clin. memo.) [Glade] 87 (Ja)
delivery, neonatal complications and, among autistic children [Deykin] 860 (Se)
Pregnancy Complications, Infectious
herpes zoster in early infancy (clin. memo.) [Dworsky] 618 (Je)
Prenatal Diagnosis
great expectations (letter from abroad) [Barrie] 901 (Se)
hygroma (cystic lymphangioma), diagnosis by ultrasound, radiological case of month [Young, Haimovici] 311 (Mr); genetic implications (letter) [Rutledge] 999, (reply) [Haimovici] 1000 (Oc)
Prescriptions, Drug
fluoride supplements for children, survey of physicians' prescription practices [Margolis] 865 (Se)
Presentation, Fetal see Labor Presentation
Pressure
'breech head' with brow presentation (clin. memo.) [Wassman] 994 (Oc)
spinal cord compression, unusual manifestation of pseudohypoparathyroidism (clin. memo.) [Cavallo] 706 (Jy)
Probability
circumcision and risk of cancer of penis, life-table analysis [Kochen] 484 (My)
Progressive Lenticular Degeneration see Hepatolenticular Degeneration
Promethazine
acute dystonic reactions induced by (clin. memo.) [Darwish] 990 (Oc)
Propanol see Alcohol, Propyl
Propoxyphene
naloxone, underdosage after narcotic poisoning [Moore] 156 (Fe)
Propranolol
complications of use in neonatal thyrotoxicosis (clin. memo.) [Newman] 707 (Jy)

Propranolol—Continued
is it alone really beneficial in neonatal thyrotoxicosis? bradycardia and hypoglycemia evoke doctrine of *primum non nocere* [Gardner] 819 (Se)
Prostaglandins
essential fatty acids revisited [Friedman] 397 (Ap)
physiologic role of, review [Olley] 688 (Jy)
Protein-Calorie Malnutrition
cell-mediated immune defects and infection, study of malnourished hospitalized children [Carney] 824 (Se)
Protein Deficiency see also Dietary Proteins
treatment of Bartter's syndrome with indomethacin [Garin] 258 (Mr)
Protein-Losing Enteropathies
apparent, associated with giardiasis (clin. memo.) [Sherman] 893 (Se)
Proteus
chronic otitis media in children, microbiological studies [Brook] 564 (Je)
Proximal Renal Tubular Dysfunction see Fanconi Syndrome
Prune Belly Syndrome
association with Turner's syndrome (clin. memo.) [Lubinsky] 1171 (De)
small intestine elongated in (letter) [Miller] (reply) [Siebert] 1182 (De)
Pseudohermaphroditism
campomelic dysplasia, further elucidation of distinct entity [Hall] 285 (Mr)
phenotypic variation in family with partial androgen insensitivity syndrome [Maes] 470 (My)
Pseudohypoparathyroidism
spinal cord compression, unusual manifestation of (clin. memo.) [Cavallo] 706 (Jy)
Pseudomonas aeruginosa
chronic otitis media in children, microbiological studies [Brook] 564 (Je)
Pseudomonas Infections
acute pulmonary exacerbations in cystic fibrosis, double-blind trial of tobramycin and placebo [Wientzen] 1134 (De)
Pseudosclerosis see Hepatolenticular Degeneration
Psychology
psychological factors in diabetes mellitus (letter) [Laron] (reply) [Greydanus] 1004 (Oc)
Psychoses, Manic-Depressive
Ebstein's anomaly of tricuspid valve associated with prenatal exposure to lithium carbonate (clin. memo.) [Park] 703 (Jy)
Pterygium
popliteal, malformation complex, spondylohypoplasia, arthrogryposis, and [Turkel] 42 (Ja), (letter) [Torres-Aybar] 1001 (Oc)
Ptosis, Eyelid see Blepharoptosis
Puberty
menarchal determinants in cystic fibrosis [Moshang] 1139 (De)
Puberty, Precocious
computerized tomography in evaluation of isosexual precocity [Hung] 25 (Ja), (letter) [Schwartz] 802 (Au)
multicystic ovaries detected by sonography in children with hypothyroidism [Lindsay] 588 (Je)
Public Relations
impact of mass media on adolescent sexual behavior, chicken or egg? [Hein] 133 (Fe)
Pulmonary Artery
familial pulmonary atresia, occurrence with ventricular septal defect [DiChiara] 506 (My)
Pulmonary Diseases see Lung Diseases
Pulmonary Heart Disease
heart failure in cystic fibrosis, treatment and prognosis of cor pulmonale with failure of right side of heart [Stern] 267 (Mr), (letter) [Marino] (reply) [Stern] 1179 (De)

Pulmonary Heart Disease—Continued
hemoglobin desaturation, occurrence during sleep in cystic fibrosis [Francis] 734 (Au)
Pulmonary Veins
pulmonary veno-occlusive disease appearing as acute, recurrent abdominal pain (clin. memo.) [Weinberg] 86 (Ja)
Puncture Biopsy see Biopsy, Needle
Purpura
anaphylactoid, eye involvement in (clin. memo.) [Lorentz] 524 (My)
role of respiratory infection in intrathoracic petechiae, implications for sudden infant death [Guntheroth] 364 (Ap)
Purpura, Thrombopenic
idiopathic, platelet antibodies disappear with recovery (letter) [Ozsoylu] 93 (Ja)
Pus see Suppuration
Pyelonephritis see Kidney Failure, Chronic
Pyloric Stenosis
hypertrophic, prognosis in operated cases of, *60 Years Ago in AJDC*, 432 (Ap)
Pyridoxine
acute isoniazid poisoning in childhood [Miller] 290 (Mr)
essential fatty acids revisited [Friedman] 397 (Ap)
5-hydroxytryptophan and, effects in young children with Down's syndrome [Pueschel] 838 (Se)
Pyrimethamine
infants potentially at risk for congenital toxoplasmosis [Stray-Pedersen] 638 (Jy)

R

Radiography
esophagogram compared to string test for gastroesophageal reflux [Liebman] 755 (Au)
many advantages of direct microfocus roentgenographic magnification in pediatric radiology, portable x-ray machine with uniquely different x-ray tube [Brodeur] 245 (Mr)
pancuronium and abnormal abdominal roentgenograms [Dillard] 821 (Se)
Radioisotope Scanning see Radionuclide Imaging
RADIOLOGICAL CASE OF MONTH
anomalous apical bronchus of right upper lobe [Young, Fujioka] 615 (Je)
cervical disk calcification in childhood [Young, Faucher] 701 (Jy)
giant cell pneumonia [Young, Ross] 511 (My)
hygroma (cystic lymphangioma), diagnosis by ultrasound [Young, Haimovici] 311 (Mr); genetic implications (letter) [Rutledge] 999, (reply) [Haimovici] 1000 (Oc)
infantile nutritional copper deficiency [Young, Bennani-Smires] 1155 (De)
intrathoracic rib [Young, Hilton] 1085 (No)
juvenile aponeurotic fibroma [Young, Lowell] 195 (Fe)
osteopoikilosis, familial documentation [Young, Gershman] 415 (Ap)
retroperitoneal lipoma in child [Young, Severson] 83 (Ja)
systemic air embolism secondary to respiratory therapy [Young, Kogutt] 983 (Oc)
traumatic ischial apophyseolysis [Young, Tan] 885 (Se)
Radiology, Diagnostic X-Ray see Radiography
Radionuclide Imaging
falsely normal scans for osteomyelitis [Fleisher] 499 (My)
isotopic cisternography in tuberculous meningitis of childhood [Ozdirim] 572 (Je)
'normal' technetium bone scans in patients with acute osteomyelitis [Berkowitz] 828 (Se)
Radiotherapy
nasal polymorphic reticulosis in child [Houghton] 387 (Ap)

Radius
craniosynostosis-radial aplasia, Baller-Gerold syndrome (clin. memo.) **133:**1279 (De), correction, **134:**363 (Ap)
Hodgkin's disease as epitrochlear adenopathy (clin. memo.) [Berman] 319 (Mr)
TAR syndrome, dorsal pedal edema and excessive perspiration (clin. memo.) [Feingold] 895 (Se)
Rapid Eye Movements see Sleep, REM
Recklinghausen's Disease of Nerve see Neurofibromatosis
Reflex
syndrome of infantile CNS degeneration [Holmes] 262 (Mr)
Refugees
"teach a man to fish" (Chinese proverb) [Sumpter] 1025 (No)
Regression
and clinical research [Brown] 549 (Je), correction, 746 (Au)
Regurgitation, Gastric see Esophageal Reflux
Renal Failure, Acute see Kidney Failure, Acute
Renal Failure, Chronic see Kidney Failure, Chronic
Renal Veins
thrombosis in neonates [Rasoulpour] 276 (Mr)
Reproduction
prostaglandins [Olley] 688 (Jy)
Research
clinical, and regression [Brown] 549 (Je), correction, 746 (Au)
Residency, Medical see Internship and Residency
Respiration, Artificial
fluid administration and bronchopulmonary dysplasia, lack of association [Spahr] 958 (Oc)
massive intracranial air embolism, complication of mechanical ventilation (clin. memo.) [Banagale] 799 (Au)
pancuronium and abnormal abdominal roentgenograms [Dillard] 821 (Se)
Respirators
hyaline membrane disease, controlled study of inspiratory to expiratory ratio in its management by ventilator [Spahr] 373 (Ap)
Respiratory Distress Syndrome see also Hyaline Membrane Disease
acute caffeine overdose in neonate [Banner] 495 (My)
early-onset sepsis and pneumonia observed as, assessment of lung maturity [Jacob] 766 (Au)
fluid administration and bronchopulmonary dysplasia, lack of association [Spahr] 958 (Oc)
group B streptococcal disease, diagnosis with use of antigen detection, Gram's stain, and presence of apnea, hypotension [Ingram] 754 (Au)
intracranial hemorrhage in premature, predictive features and outcome [Kosmetatos] 855 (Se)
liver herniation presenting as cardiomegaly and (clin. memo.) [Hofschire] 1091 (No)
massive intracranial air embolism, complication of mechanical ventilation (clin. memo.) [Banagale] 799 (Au)
Respiratory Failure see Respiratory Insufficiency
Respiratory Insufficiency
lidocaine ingestion (clin. memo.) [Sakai] 323 (Mr)
Respiratory System
foreign body in airway, review of 200 cases [Blazer] 68 (Ja)
Respiratory Tract Infections
bacillus of Pfeiffer in inflammations of respiratory tract in children, *60 Years Ago in AJDC*, 614 (Je)
role in intrathoracic petechiae, implications for sudden infant death [Guntheroth] 364 (Ap)
transient "lazy-leukocyte" syndrome during infancy [Yoda] 467 (My)
Reticuloendothelial System
nasal polymorphic reticulosis in child [Houghton] 387 (Ap)
Retroperitoneal Neoplasms
cerebellar ataxia, opsoclonus, and occult neural crest tumor, abdominal computerized tomography in diagnosis [Kinast] 1057 (No)
lipoma in child, radiological case of month [Young, Severson] 83 (Ja)
REVIEW
acute febrile mucocutaneous lymph node syndrome [Yanagihara] 603 (Je)
acute iron poisoning [Robotham] 875 (Se)
bacterial immunizations [Harrison] 184 (Fe)
food sensitivity, critical review and practical approach [Bock] 973 (Oc)
hypernatremic dehydration of infancy, epidemiologic review [Paneth] 785 (Au), correction, 1096 (No)
prostaglandins [Olley] 688 (Jy)
vegetarianism in children [MacLean] 513 (My)
vitamin E and neonate [Ehrenkranz] 1157 (De)
Reviewers
Honor Roll for 1979, 85 (Ja)
Reye's Syndrome
and pancreatitis (letter) [Gilboa] 903 (Se)
associated with disseminated intravascular coagulation and acute renal failure (letter) [Muntean] 999 (Oc)
in 3 siblings, association with type A influenza infection [Wilson] 1032 (No)
Rhomboencephalic Sleep see Sleep, REM
Ribs
intrathoracic rib, radiological case of month [Young, Hilton] 1085 (No)
Rickets
X-linked hypophosphatemic, role of supranormal 25-hydroxyvitamin D and subnormal 1,25-dihydroxyvitamin D in [Chesney] 140 (Fe)
Rifadin see Rifampin
Rifampicin see Rifampin
Rifampin
aspergillosis in chronic granulomatous disease, therapeutic considerations (clin. memo.) [Corrado] 1092 (No)
Rimactane see Rifampin
Risk see Probability
Ritter's Disease see Dermatitis Exfoliativa
RNA Viruses
rotavirus gastroenteritis in Washington, DC, area, incidence of cases resulting in admission to hospital [Rodriguez] 777 (Au)
Rodenticides
Vacor (PNU), accidental ingestion of, symptoms and sequelae [Johnson] 161 (Fe), (letter) [LeWitt] 1178 (De)
Roentgenography see Radiography
Rolcaltrol see Calcitriol
Romberg's Disease see Facial Hemiatrophy
Rotavirus see RNA Viruses
Rothmund-Thomson Syndrome
with severe dwarfism [Hall] 165 (Fe)
Rubella Vaccine
commentary on immunization [Shaw] 130 (Fe)
RA27/3, 4-year follow-up [Balfour] 350 (Ap)
Rubeola see Measles
Rural Health
human toxocariasis in rural community [Jones] 967 (Oc)

S

Sacrum
occult anterior sacral meningocele [Sumner] 385 (Ap)
Saggital Sinus
improved needle for sinus therapy, *60 Years Ago in AJDC*, 327 (Mr)
Salicylates
new thoughts on aspirin [Baum] 455 (My)
therapy in juvenile rheumatoid arthritis, dose, serum level, and toxicity [Doughty] 461 (My)
Saliva
immunoglobulin concentrations in duodenal fluid of infants and children [Lebenthal] 834 (Se)
Salivary Gland Viruses see Cytomegaloviruses
Salmonella Infections
breast-feeding and [France] 147 (Fe)
Sarcoma, Ewing's
progressive facial hemiatrophy associated with [Paradise] 1065 (No)
Scabies
neonatal (letter) [Dolezal] (reply) [Burns] 1003 (Oc)
Scanning, Radioisotope see Radionuclide Imaging
Schools
injuries in high school physical education classes [Austin] 456 (My)
Schwartz-Bartter Syndrome see Inappropriate ADH Syndrome
Scintigraphy see Radionuclide Imaging
Sclerosis, Hereditary Spinal see Friedreich's Ataxia
Selenium
trace elements in fetus and young infant [Shaw] 74 (Ja)
Self Concept
women who abuse their children, implications for pediatric practice [Rosen] 947 (Oc)
Septicemia
acute glossitis and, owing to *Haemophilus influenzae* type B (clin. memo.) [San Joaquin] 91 (Ja)
anaerobic bacteremia in children [Brook] 1052 (No)
bacteremias due to *Haemophilus influenzae* and *Streptococcus pneumoniae*, occurrence and course in children with cancer [Siber] 668 (Jy)
Clostridium infection in mother and infant (clin. memo.) [Chaney] 1175 (De)
diphtheroid sepsis in child with no predisposing condition (clin. memo.) [MacDonald] 708 (Jy)
early-onset sepsis and pneumonia observed as respiratory distress syndrome, assessment of lung maturity [Jacob] 766 (Au)
fatal group G streptococcal sepsis in preterm neonate (clin. memo.) [Mohan] 894 (Se)
fulminant neonatal meningococcemia [Clegg] 354 (Ap)
hydrops of gallbladder (clin. memo.) [Neu] 891 (Se)
hyperglycemia and sepsis in newborn (letter) [Kramer] (reply) [James] 427 (Ap)
metastatic complications of *Fusobacterium necrophorum* sepsis, 2 cases of Lemierre's postanginal septicemia [Vogel] 356 (Ap)
nosocomial transmission of bacteriophage type 7/11/12 group B streptococci in special care nursery [Boyer] 964 (Oc)
Staphylococcus aureus sepsis in childhood malignancy [Miser] 831 (Se)
Sex Behavior
adolescent, impact of mass media on, chicken or egg? [Hein] 133 (Fe)
Sex Chromosome Abnormalities
live-born triploid (clin. memo.) [Fraikor] 988 (Oc)
Sex Chromosomes
triplo-X and Down's syndrome (letter) [Yeatman] (reply) [Gardner] 527 (My)
Sex Factors
mortality and sex difference (letter) [Waldron] 999 (Oc)
Sex Offenses
sexual abuse of boys [Ellerstein] 255 (Mr), (letter) [Duncan] 1001 (Oc)
SGOT see Aspartate Aminotransferase
Sheehan's Syndrome see Hypopituitarism
Shock, Anaphylactic see Anaphylaxis
SIADH see Inappropriate ADH Syndrome

Simmonds' Disease see Hypopituitarism
60 YEARS AGO IN AJDC
active immunization against diphtheria in large child-caring institution, 637 (Jy)
bacillus of Pfeiffer in inflammations of respiratory tract in children, 614 (Je)
bodily mechanics, relation to cyclic vomiting and other obscure intestinal conditions, 907 (Se)
dextrose tolerance in atrophic infants, 45 (Ja)
elimination of acetone bodies during infectious fevers, 158 (Fe)
improved needle for sinus therapy, 327 (Mr)
pneumococcus peritonitis in infancy and early childhood, 1045 (No)
polyneuritic syndrome resembling pellegra-acrodynia (?) seen in very young children, 1064 (No)
prognosis in operated cases of hypertrophic stenosis of pylorus, 432 (Ap)
some phases of pathology of nutrition in infancy, 1177 (De)
study of pneumonia in infancy and childhood during recent epidemics [Heiman] 740 (Au)
water retention in pneumonia, 478 (My)
Skin
cutaneous necrosis associated with intravenous nafcillin therapy [Tilden] 1046 (No)
Skin Diseases
Rothmund-Thomson syndrome with severe dwarfism [Hall] 165 (Fe)
Skin Diseases, Bullous
danger of 50-mg dapsone doses to children (letter) [Kahn] (reply) [Jarratt] 623 (Je)
Skin Manifestations
juvenile chronic granulocytic leukemia, emphasis on underlying neurofibromatosis and [Mays] 654 (Jy)
Skin Neoplasms
Ota's nevus, picture of month [Gellis, Fikar] 1083 (No)
Skin Tests
diphtheria-tetanus skin testing, clinical value for delayed hypersensitivity [Kaufman] 479 (My)
food sensitivity, critical review and practical approach [Bock] 973 (Oc)
Skull
sector scan ultrasound imaging through anterior fontanelle, use in diagnosing neonatal periventricular-intraventricular hemorrhage [Allan] 1028 (No)
Sleep
hemoglobin desaturation, occurrence in cystic fibrosis during [Francis] 734 (Au)
hypoxemia in patients with cystic fibrosis [Mansell] 733 (Au)
hypoxemia in young adults with cystic fibrosis [Stokes] 741 (Au)
Sleep, REM
hemoglobin desaturation, occurrence in patients with cystic fibrosis during [Francis] 734 (Au)
hypoxemia in patients with cystic fibrosis [Mansell] 733 (Au)
hypoxemia in young adults with cystic fibrosis [Stokes] 741 (Au)
Socialized Medicine see State Medicine
Sodium see also Hypernatremia; Hyponatremia
plasma adrenocorticotrophic hormone in congenital adrenal hyperplasia, importance in long-term management [LaFranchi] 1068 (No)
Soft Tissue Neoplasms
juvenile aponeurotic fibroma, radiological case of month [Young, Lowell] 195 (Fe)
Somatostatin
metabolic studies in child with pancreatic insulinoma [Ginsberg-Fellner] 64 (Ja)
Somatotropin
isolated growth hormone deficiency and cystic fibrosis (clin. memo.) [Hubbard] 317 (Mr)
topically applied testosterone and phallic growth, effect in male children with hypopituitarism and microphallus [Ben-Galim] 296 (Mr)
Sore Throat see Pharyngitis
Soy Beans
nutritional osteomalacia (letter) [Elinson] 427 (Ap)
Spectinomycin
therapy for gonorrhea in prepubertal children [Rettig] 359 (Ap)
Spermatic Cord Torsion
intrauterine, bilaterally enlarged testicles in newborn, atypical presentation of (clin. memo.) [Gerstmann] 992 (Oc)
Sphaerophorus necrophorus see Fusobacterium necrophorum
Spinal Cord see Myelography
Spinal Cord Compression
unusual manifestation of pseudohypoparathyroidism (clin. memo.) [Cavallo] 706 (Jy)
Spinal Puncture
brachial plexus neuropathy [Charles] 299 (Mr), (letter) [Bale] 903 (Se)
Spine
malformation complex, spondylohypoplasia, arthrogryposis, and popliteal pterygium [Turkel] 42 (Ja), (letter) [Torres-Aybar] 1001 (Oc)
Spleen
normal, in newborn, successful treatment of rupture of (clin. memo.) [Chryss] 418 (Ap)
Splenectomy
successful treatment of rupture of normal spleen in newborn (clin. memo.) [Chryss] 418 (Ap)
Splenic Rupture
spontaneous, in acute lymphoblastic leukemia, successful nonoperative management (clin. memo.) [Soorya] 201 (Fe)
successful treatment of rupture of normal spleen in newborn (clin. memo.) [Chryss] 418 (Ap)
Sprains and Strains
injuries in high school physical education classes [Austin] 456 (My)
Stains and Staining
group B streptococcal disease, diagnosis with use of antigen detection, Gram's stain, and presence of apnea, hypotension [Ingram] 754 (Au)
Staphylococcal Infections
acute pulmonary exacerbations in cystic fibrosis, double-blind trial of tobramycin and placebo [Wientzen] 1134 (De)
nosocomial scalded skin syndrome, Ritter's disease caused by phage group 3 *S aureus* [Florman] 1043 (No)
Staphylococcus aureus
adherence of, to infant nasal mucosal cells (clin. memo.) [Aly] 522 (My)
chronic otitis media in children, microbiological studies [Brook] 564 (Je)
sepsis in childhood malignancy [Miser] 831 (Se)
State Medicine
fate of Special Care Baby Unit in London (letter from abroad) [Barrie] 431 (Ap)
Statistics
regression and clinical research [Brown] 549 (Je), correction, 746 (Au)
Steely Hair Syndrome see Kinky Hair Syndrome
Still's Disease see Arthritis, Juvenile Rheumatoid
Stomach
surgical treatment of gastroesophageal reflux in children, results of Nissen's fundoplication in 100 children [Leape] 935 (Oc)
Streptococcal Infections
acute glomerulonephritis and skin lesions in Eskimo children [Margolis] 681 (Jy)
fatal group G sepsis in preterm neonate (clin. memo.) [Mohan] 894 (Se)
group B, diagnosis with use of antigen detection, Gram's stain, and presence of apnea, hypotension [Ingram] 754 (Au)
hydrops of gallbladder (clin. memo.) [Neu] 891 (Se)
neonatal osteomyelitis (letter) [Lai] 711 (Jy)
Streptococcal Infections—Continued
nosocomial transmission of bacteriophage type 7/11/12 group B streptococci in special care nursery [Boyer] 964 (Oc)
Streptococcus
antibiotic-resistant (letter) [Gentry] 801 (Au)
Streptococcus aureus
disparate cultures of middle ear fluids, results from children with bilateral otitis media [Pelton] 951 (Oc)
Streptococcus Group A see Streptococcus pyogenes
Streptococcus pneumoniae
bacteremias due to *Haemophilus influenzae* and, occurrence and course in children with cancer [Siber] 668 (Jy)
Streptococcus pyogenes
group A β-hemolytic streptococci causing pyogenic gingival cyst in infancy (clin. memo.) [Patamasucon] 617 (Je)
Strychnine
nonketotic hyperglycinemia, effects of therapy with [Warburton] 273 (Mr)
Subarachnoid Space
occult anterior sacral meningocele [Sumner] 385 (Ap)
Succinates
argininosuccinicaciduria, hair abnormality revisited (clin. memo.) [Potter] 1095 (No)
Suction
esophageal perforations in premature infants, comments on diagnosis [Clarke] 367 (Ap)
use of side-hole endotracheal tube adapter for tracheal aspiration [Zmora] 250 (Mr)
Sulfadiazine
infants potentially at risk for congenital toxoplasmosis [Stray-Pedersen] 638 (Jy)
Sulfamethoxazole
trimethoprim with, chemoprophylaxis for *Pneumocystis carinii* pneumonitis [Wilber] 643 (Jy)
trimethoprim with, continuous therapy in prevention of *Pneumocystis* pneumonia [Harris] 35 (Ja)

Expressly for kids with colds that cough*

orange-pineapple flavored

Tuss-Ornade® cough/cold liquid

Each 5 ml. teaspoonful contains 5 mg. caramiphen edisylate; 2 mg. chlorpheniramine maleate; 15 mg. phenylpropanolamine hydrochloride; isopropamide iodide equivalent to 0.75 mg. of isopropamide; and alcohol, 7.5%.

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

* **INDICATIONS**

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Lacking in substantial evidence of effectiveness as a fixed combination: For relief from coughing, upper respiratory congestion and hypersecretion associated with the common cold, sinusitis, vasomotor rhinitis and allergic rhinitis.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Hypersensitivity to any component; concurrent MAO inhibitor therapy; severe hypertension; bronchial asthma; coronary artery disease; stenosing peptic ulcer; pyloroduodenal or bladder neck obstruction. Do not use 'Tuss-Ornade' Liquid in children less than six months of age or under 15 lbs. in weight. Do not use 'Tuss-Ornade' *Spansule* capsules in children under 12 years of age.

Warnings: Warn vehicle or machine operators of possible drowsiness. Warn patients of possible additive effects of alcohol and other C.N.S. depressants.

Usage in Pregnancy: Use in pregnancy, nursing mothers and women who might bear children only when potential benefits have been weighed against possible hazards. An inhibitory effect on lactation may occur.

Effect on PBI Determination and I^{131} Uptake: The iodine in isopropamide iodide may alter PBI test results and will suppress I^{131} uptake; use thyroid tests unaffected by exogenous iodides.

Precautions: Use with caution in persons with cardiovascular disease, glaucoma, prostatic hypertrophy, hyperthyroidism. 'Tuss-Ornade' Liquid contains FD&C Yellow #5 (tartrazine), which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow #5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

Adverse Reactions: Drowsiness; excessive dryness of nose, throat or mouth; nervousness, insomnia; nausea, vomiting, diarrhea; rash; dizziness; weakness; tightness of chest; angina pain; abdominal pain; irritability; palpitation; headache; incoordination; tremor; difficulty in urination; thrombocytopenia, leukopenia; convulsions; hypertension, hypotension; anorexia; constipation; visual disturbances; iodine toxicity (acne, parotitis); dysuria; epigastric distress.

Supplied: 'Tuss-Ornade' Liquid: An orange-pineapple flavored liquid in 16 fl. oz. bottles. For patients 12 years or older, 'Tuss-Ornade' *Spansule* capsules (each capsule contains 20 mg. caramiphen edisylate; 8 mg. chlorpheniramine maleate; 50 mg. phenylpropanolamine HCl; and isopropamide iodide equivalent to 2.5 mg. of isopropamide), in bottles of 50 and 500 capsules.

Ilosone® (erythromycin estolate)

WARNING

Hepatic dysfunction with or without jaundice has occurred, chiefly in adults, in association with erythromycin estolate administration. It may be accompanied by malaise, nausea, vomiting, abdominal colic, and fever. In some instances, severe abdominal pain may simulate an abdominal surgical emergency.

If the above findings occur, discontinue Ilosone promptly.

Ilosone is contraindicated for patients with a known history of sensitivity to this drug and for those with preexisting liver disease.

Indications: *Streptococcus pyogenes* (Group A Beta-Hemolytic) – Upper and lower respiratory tract, skin, and soft-tissue infections of mild to moderate severity.

Injectable penicillin G benzathine is considered by the American Heart Association to be the drug of choice in the treatment and prevention of streptococcal pharyngitis and in long-term prophylaxis of rheumatic fever.

When oral medication is preferred for treating the above-mentioned conditions, penicillin G or V or erythromycin is the alternate drug of choice.

The importance of the patient's strict adherence to the prescribed dosage regimen must be stressed when oral medication is given. A therapeutic dose should be administered for at least ten days.

Alpha-Hemolytic Streptococci (Viridans Group) – Short-term prophylaxis against bacterial endocarditis prior to dental or other operative procedures in patients with a history of rheumatic fever or congenital heart disease who are hypersensitive to penicillin. (Erythromycin is not suitable prior to genitourinary surgery when the organisms likely to lead to bacteremia are gram-negative bacilli or belong to the enterococcus group of streptococci.)

Staphylococcus aureus – Acute infections of skin and soft tissue which are mild to moderately severe. Resistance may develop during treatment.

S. (Diplococcus) pneumoniae – Infections of the upper respiratory tract (e.g., otitis media, pharyngitis) and lower respiratory tract (e.g., pneumonia) of mild to moderate severity.

Mycoplasma pneumoniae (Eaton Agent, PPLO) – Respiratory tract infections due to this organism.

Haemophilus influenzae – May be used concomitantly with adequate doses of sulfonamides for upper respiratory tract infections of mild to moderate severity. Not all strains of this organism are susceptible at the erythromycin concentrations ordinarily achieved.

Treponema pallidum – As an alternate treatment in penicillin-allergic patients. In primary syphilis, spinal-fluid examinations should be done before treatment and as part of follow-up after therapy.

Corynebacterium diphtheriae – As an adjunct to antitoxin, to prevent establishment of carriers, and to eradicate the organism in carriers.

C. minutissimum – In the treatment of erythrasma.

Entamoeba histolytica – For intestinal amebiasis only. Extraenteric amebiasis requires treatment with other agents.

Listeria monocytogenes – Infections due to this organism.

Legionnaires' Disease – Although no controlled clinical efficacy studies have been conducted, in vitro and limited preliminary clinical data suggest that erythromycin may be effective in treating Legionnaires' disease.

Contraindication: Known hypersensitivity to this antibiotic.

Warnings: (*See* Warning box above.) The administration of erythromycin estolate has been associated with the infrequent occurrence of cholestatic hepatitis. Laboratory findings have been characterized by abnormal hepatic function test values, peripheral eosinophilia, and leukocytosis. Symptoms may include malaise, nausea, vomiting, abdominal cramps, and fever. Jaundice may or may not be present. In some instances, severe abdominal pain may simulate the pain of biliary colic, pancreatitis, perforated ulcer, or an acute abdominal surgical problem. In other instances, clinical symptoms and results of liver function tests have resembled findings in extrahepatic obstructive jaundice.

Initial symptoms have developed in some cases after a few days of treatment but generally have followed one or two weeks of continuous therapy. Symptoms reappear promptly, usually within 48 hours after the drug is readministered to sensitive patients. The syndrome seems to result from a form of sensitization, occurs chiefly in adults, and has been reversible when medication is discontinued.

Usage in Pregnancy – Safety of this drug for use during pregnancy has not been established.

Precautions: Caution should be exercised in administering this antibiotic to patients with impaired hepatic function.

Recent studies of erythromycin reveal that its use in patients receiving high doses of theophylline may be associated with an increase in serum theophylline levels and potential theophylline toxicity. In such a case, the dose of theophylline should be reduced while the patient is receiving concomitant erythromycin therapy.

Surgical procedures should be performed when indicated.

Adverse Reactions: The most frequent side effects are gastrointestinal (e.g., abdominal cramping and discomfort) and are dose related. Nausea, vomiting, and diarrhea occur infrequently with usual oral doses.

During prolonged or repeated therapy, overgrowth of nonsusceptible bacteria or fungi is possible. If such infections arise, the drug should be discontinued and appropriate therapy instituted.

Mild allergic reactions, such as urticaria and other skin rashes, have occurred. Serious allergic reactions, including anaphylaxis, have been reported. [0130791]

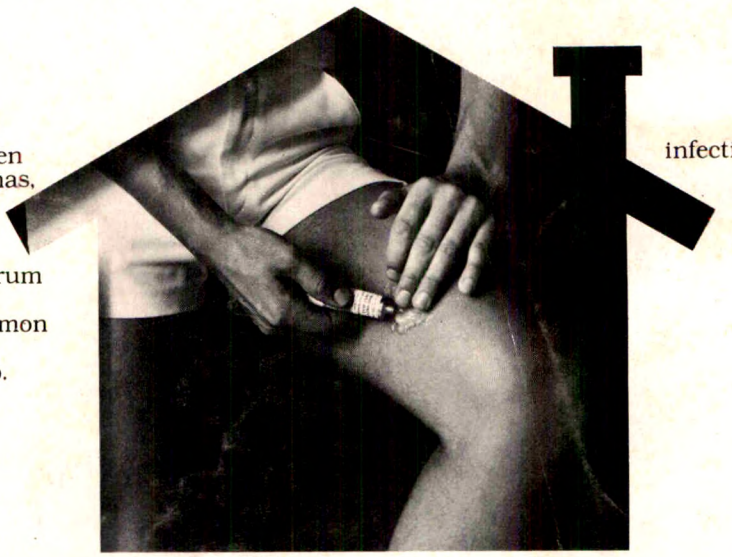
works just as well in their homes.



- It's effective therapy for abrasions, lacerations, open wounds, primary pyodermas, secondarily infected dermatoses.
- It provides broad-spectrum overlapping antibacterial effectiveness against common susceptible pathogens, including staph and strep.
- It helps prevent topical infections, and treats those that have already started.
- It contains three antibiotics that are rarely used systemically.
- It is convenient to recommend without a prescription.

NEOSPORIN® Ointment—for the office, for the home.

(polymyxin B-bacitracin-neomycin)

Effective • Economical • Convenient • Recommendable

Each gram contains: Aerosporin® (Polymyxin B Sulfate) 5,000 units, bacitracin zinc 400 units, neomycin sulfate 5 mg (equivalent to 3.5 mg neomycin base); special white petrolatum qs; in tubes of 1 oz and 1/2 oz and 1/32 oz (approx.) foil packets.

WARNING: Because of the potential hazard of nephrotoxicity and ototoxicity due to neomycin, care should be exercised when using this product in treating extensive burns, trophic ulceration and other extensive conditions where absorption of neomycin is possible. In burns where more than 20 percent of the body surface is affected, especially if the patient has impaired renal function or is receiving other aminoglycoside antibiotics concurrently, not more than one application a day is recommended.

When using neomycin-containing products to control secondary infection in the chronic dermatoses, it should be borne in mind that the skin is more liable to become sensitized to many substances, including neomycin. The manifestation of sensitization to neomycin is usually a low grade reddening with swelling, dry scaling and itching; it may be manifest simply as a failure to heal. During long-term use of neomycin-containing products, periodic examination for such signs is advisable and the patient should be told to discontinue the product if they are observed. These symptoms regress quickly on withdrawing the medication. Neomycin-containing applications should be avoided for that patient thereafter.

PRECAUTIONS: As with other antibacterial preparations, prolonged use may result in overgrowth of non-susceptible organisms, including fungi. Appropriate measures should be taken if this occurs.

ADVERSE REACTIONS: Neomycin is a not uncommon cutaneous sensitizer. Articles in the current literature indicate an increase in the prevalence of persons allergic to neomycin. Ototoxicity and nephrotoxicity have been reported (see Warning section).
